Physitu parameters such as

# herbicides, oil and grease, organic matter and heavy metals. Biological parameters monitored included fecal bacteria, phytoplankton, zooplankton, macroinvertebrates and aquatic macrophytes. Algal nutrient limitation was evaluated using the U. S. EPA Algal Assay Bottle Test. The physical-chemical water quality of the Middle Black Warrior and Tombigbee River evidenced no levels of monitored constituents which would be considered severe or environmentally degrading. The river and reservoirs exhibited only very minor seasonal stratification. Seasonal variation in certain constituents most notably suspended matter, nutrients and some unions, was observed and resulted primarily through increased discharge due or rainfall. Aquatic biota was observed to be relatively diverse and indicative of moderate to good biological water quality.

#### **ABSTRACT**

The U.S. Army Corps of Engineers, Mobile District contracted Harmon Engineering & Testing of Auburn, Alabama, to perform a Water Quality Management Study of the Middle Black Warrior and Tombigbee River System (Contract No. DACW01-78-0181). The study began in July 1978, and samplings were made approximately every six weeks through October 1979, for a total of thirteen (13) samplings. Physical-chemical water quality parameters including in-situ parameters such as temperature and dissolved oxygen were measured along with anions, cations, and heavy metals. Sediment samples were analyzed for grain size, pesticides, herbicides, oil and grease, organic matter and heavy metals. Biological parameters menitored included fecal bacteria, phytoplankton, zooplankton, macroinvertebrates and aquatic macrophytes. Algal nutrient limitation was evaluated using the U.S. EPA Algal Assay Bottle Test.

The physical-chemical water quality of the Middle Black Warrior and Tombigbee River evidenced no levels of monitored constituents which would be considered severe or environmentally degrading. The river and reservoirs exhibited only very minor seasonal stratification. Seasonal variation in certain constituents, most notably suspended matter, nutrients and some anions, was observed and resulted primarily through increased discharge due to rainfall. Aquatic biota was observed to be relatively diverse and indicative of moderate to good biological water quality.

#### **EXECUTIVE SUMMARY**

The Water Quality Management Study of the Middle Black Warrior and Tombigbee River basins (Contract No. DACW01-78-0181) indicated that this dual river basin, which includes the reservoirs impounded by Warrior Lock and Dam and Demopolis Lock and Dam, had no physical, chemical or biological water quality conditions which would be considered environmentally degrading. This indication resulted from an eighteen (18) month water quality survey conducted at twenty-three (23) stations throughout the two river basins. The following sections provide a synopsis of the study and the results and conclusions obtained.

#### STUDY AREA

The Middle Black Warrior and Tombigbee River System includes the Black Warrior River from Oliver Lock and Dam at Tuscaloosa to its confluence with the Tombigbee River near Demopolis. The Tombigbee River section considered in this study began at Gainesville Dam and continued to Demopolis Lock and Dam. There were sixteen (16) ronitoring stations on the Black Warrior River, five (5) on the Tombigbee River and two (2) in Demopolis Lake. Additionally, twelve (12) major tributary streams were monitored, along with six (6) municipal and industrial discharges.

#### ANALYSES AND ANALYTICAL METHODS

Throughout the study, approximately one hundred (100) different parameters were measured and analyzed. These included physical measurements, in-situ chemical measurements, laboratory analyses, biological specimen collection, identification and enumeration and field observation of aquatic plants. Each different segment of the study was performed according to methodologies agreed upon by the U.S. Army Corps of Engineers, Mobile District. Laboratory quality control procedures were used to maintain the validity of the analytical results.

Physical measurements were temperature and light penetration. In-situ chemical measurements were performed for pH, specific conductance, dissolved oxygen and oxidation reduction potential. Laboratory parameter included a full range of anions, nutrients and heavy metals. Biological parameters were fecal bacteria, phytoplankton, zooplankton, macroinvertebrates and aquatic macrophytes.

In addition to routine collection of water quality data, several other investigations were performed. Sediments were collected for physical-chemical analyses. The in-situ chemical measurements were used to monitor for stratification, tributary and discharge quality and the water quality effect of operating Warrior Lock.

#### **RESULTS**

In-situ analysis showed that the Middle Black Warrior and Tombigbee River basin were relatively warm (9° - 31°c) and well oxygenated (surface dissolved oxygen levels >5.0 mg/£). Specify conductance varied between the two basins, with the Tombigbee River having lower conductivities ( $\bar{\chi}$  = 125 µmhos/cm) than the Black Warrior River ( $\bar{\chi}$  = 175 µmhos/cm). Clarity, as measured by color, turbidity, and light transmittance and Secchi depth was generally greater in the Black Warrior River than the Tombigbee River and Demopolis Lake. This was attributable to higher turbidities and suspended solids in the Tombigbee River.

The chemical constituents of the two rivers showed varying concentrations when the study period averages are compared. Dissolved solids and the constituents varying slightly between the two river basins. The Black Warrior River had lower study period averages for alkalinity, calcium, magnesium and chlorides than did the Tombegbee River. However, the Black Warrior River had greater levels of magnesium, potassium and sodium which lead to higher total EDTA hardness and dissolved solids than occurred in the Tombigbee River. Sulfates averaged the highest levels in the Black Warrior River and sulfides were equal in both basins. Inorganic nitrogen forms were highest in the Black Warrior River while the Tombigbee River had the highest levels of organic nitrogen. Both total and dissolved phosphorus forms were highest in the Tombigbee River. Iron was more prevalent in the Tombigbee River; mangenese and zinc had their highest levels in the Black Warrior River. These results indicate that while results vary between the basins the range of variation is not tremendous (many parameters showed less than 50% variation) and no constituent poses any environmental hazard.

Biological analyses showed relatively equal numbers and diversity within the major categories studied. Phytoplankton, zooplankton and macroinvertebrates were observed to fluctuate with the seasons. Additionally, the plankton samples from Warrior Lake and Demopolis Lake showed some variations in total numbers which indicated that impoundment had some affect on production as compared to the more free flowing sections of the study area. The microbiological parameters indicated that there as a degree of fecal pollution entering the river system and the Tombigbee River showed greater levels of fecal bacteria.

Sediment analyses revealed that the two river basins had some measurable quantities of sediment-associated pollutants. Organic matter, oil and grease and nutrients did not appear to be excessively high at any of the stations monitored. Heavy metals, especially toxic metals such as cadmium, chromium, and nickel occassionally showed elevated levels, particularly below Oliver Lock and Dam and Warrior Lock and Dam. If future waterway maintenance requires dredging in these areas, special sediment quality evaluations may be necessary.

The Middle Black Warrior and Tombigbee River System evidenced very little seasonal stratification in temperature and dissolved

oxygen. The majority of stratification monitoring data indicate that both rivers present a nearly homogenous thermal and chemical profile for in-situ parameter. The lack of extensive horizontal stratification indicates that the river mixes well and that the assimilative capacity for municipal and industrial discharges was quite high.

#### **CONCLUSIONS AND RECOMMENDATIONS**

The Water Quality Management Study of the Middle Black Warrior and Tombigbee Rivers indicated that no excessive pollution was adversely affecting the water quality within the study area. Water and sediment quality and aquatic biota all appeared to be within tolerable limits. It was recommended that in the future fewer water quality monitoring stations could be established and trends in water quality could be assessed from the baseline data of this study. The implementation of such an approach, would provide a continuous record of water quality before and after completion of the Tennessee-Tombigbee Waterway.

#### SECTION 1

#### INTRODUCTION

The United States Army Corps of Engineers, Mobile District (COE) has undertaken a water quality management study for the Middle Black Warrior and Tombigbee Rivers, including Warrior Lake and Demopolis Lake. Harmon Engineering & Testing Company (HE&T) was contracted by the COE (Contract DACWO1-78-C-0181) to perform the required sampling, analyses and reporting for those impoundments.

#### 1.1 PROJECT DESCRIPTION

#### 1.1.1 Black Warrior River

The Black Warrior River is formed by the junction of Mulberry Fork and Locust Fork about 20 miles west of Birmingham, Alabama, on the Cumberland Plateau (Figure 1-1). It flows southwesterly for 174 miles through the Coastal Plain to join the Tombigbee River at Demopolis, Alabama. The river basin is the largest in Alabama with a drainage area of 6300 square miles covering all or part of sixteen counties (AWIC, 1976).

After exiting the Warrior Coal Basin north of Tuscaloosa, the river enters the study area considered in this report. This study area begins at Tuscaloosa, immediately downstream of William B. Oliver Lock and Dam (Figure 1-2). Tuscaloosa is in the Fall Line Hill Subdivision of East Gulf Coastal Plain. Near Eutaw, Alabama, the river flows into the Black Prairie Belt, which is characterized by chalk deposits of various types, and remains in this physiographic region until its end at Demopolis. Downstream of Tuscaloosa, the river averages a drop of 0.5 feet per mile and has steep, high banks.

The Black Warrior River is impounded 261.1 miles above Mobile (50 miles above the confluence with the Tombigbee River) by Warrior Lock. The Warrior reservoir covers 7,800 acres at a normal pool elevation of 95.0 feet above mean sea level (MSL) and extends 77 miles upstream to William Bacon Oliver Lock and Dam creating approximately 300 miles of shoreline. The drainage area above Warrior Lock and Dam is 6,280 square miles. The river had an average flow (1932-1955) of 8,766 cubic feet per second (cfs) and had a minimum mean monthly flow in October 1935 of 177 cfs and a maximum mean monthly flow of 44,610 in February, 1956 (U.S. Army Corps of Engineers, Mobile District, July 1975).

#### 1.1.2 Tombigbee River

The Tombigbee River originates in northeast Mississippi and flows through the Black Prairie Belt to its confluence with the Black Warrior River at Demopolis (Figure 1-1). The river continues to the confluence of the Alabama River where it forms the Mobile River which flows into Mobile Bay. The total drainage area above Demopolis Lock and Dam is 15,400 square miles (includes Black Warrior and Tombigbee River basins).

- ▲ BACTERIOLOGICAL STATION

R-10 thru R-16 = Lower Black Warrior River

R-17 thru R-21 = Tombigbee River

R-22 thru R-23 = Demopolis Lake

The study area on the Tombigbee River extends from Gainesville Lock and Dam for 52 miles downstream to Demopolis Lock and Dam forming Demopolis Lake (Figure 1-3) which is impounded 213.2 miles above Mcbile. The reservoir has a normal operating pool of 73 feet M.L. At this elevation the reservoir covers 10,000 acres, has 500 miles of shoreline and provides navigable depths to Gainesville Lock and Dam on the Tombigbee River and Warrior Lock and Dam on the Black Warrior River. Demopolis Lake had a mean flow (1928 to 1967) of 22,100 cfs; minimum monthly flow was 753 cfs in August 1954; maximum monthly flow was 116,000 cfs in March 1929 (U.S. Army Corps of Engineers, Mobile District, February 1979).

#### 1.2 OBJECTIVES

The objectives of the water quality management study on the described sections of the Middle Black Warrior and Tombigbee Rivers were:

- To establish base-line conditions for further comparisons
- To identify water quality-environmental problems
- To collect data to allow guidance for reservoir control-discharge water quality relationships
- To collect data that will provide an adequate data base and understanding of project conditions to facilitate coordination with state agencies to implement watershed pollution control.

#### 1.3 SAMPLING LOCATIONS

Figure 1-1 illustrates the general geographic location of Black Warrior and Tombigbee Rivers and the study area. Station locations for the study are shown on Figures 1-2 and 1-3.

Table 1-1 provides a listing of the main river sampling station locations of this project. Included are the STORET station codes, river miles, and brief descriptions of the station locations. The division of the table into the Black Warrior River, Tombigbee River and Demopolis Lake will facilitate discussion in later sections of this report. Table 1-2 shows similar information for the discharge and tributary stations. Table 1-3 presents the bacteriological sampling station locations.

The two river basins have been grouped into four river sections to facilitate discussion of water quality trends. Thus, the Black Warrior River has been divided and the sections designated Warrior Lake and the Lower Black Warrior River. The Tombigbee River and Demopolis Lake are the remaining sections. These section designations are fully described in Section 3 of this report.

#### 1.4 SAMPLING SCHEDULES

Table 1-4 presents a summary of the dates and sampling trips. Table 1-5 compares the main river stations to the parameters to be analyzed. Table 1-6 presents the analytical schedule for the study.

#### SECTION 2

#### **METHODS**

A detailed discussion of field sampling methods, equipment, shipping and storage methods, and analytical and biological procedures was prepared and submitted to the U.S. Army Corps of Engineers, Mobile District. The manual was prepared prior to the iniation of sampling to document all procedures. Table 2-1 summarizes that manual, tabulates and includes parameter abbreviations, Environmental Protection Agency (EPA) parameter STORET codes, analytical detection limits, units of measurement, methods of analysis, procedure reference, sample container and preservations and sample holding times. The parameters evaluated during this study are listed in the left column.

Quality assurance measures used throughout this study are based upon recommendations given in EPA's "Handbook for Analytical Quality Control in Water and Wastewater Laboratories," (1972) and recommendations from the Corps of Engineers Waterways Experiment Station. Data generation, transfer, and reporting procedures for this entire study are as follows: data collected in the field were logged into a bound field notebook; after field data are transferred to printed data sheets, the field notebook for that particular sampling period is put on file at Harmon Engineering & Testing; data generated in the laboratory are transferred from the bound bench notebook assigned to each technician to printed data sheets for report purposes; data are transferred to a STORET worksheet for computer card keypunch; and after keypunching, the data is entered into STORET by the COE.

#### 2.1 PHYSICAL-CHEMICAL

#### 2.1.1 Water

#### 2.1.1.1 Sampling

As shown in Tables 1-5 and 1-6, a wide range of parameters were measured and analyzed during this study. In-situ measurements were performed at each main river station during each trip. Further in-situ measurements were made at the tributary and discharge stations. Water samples were collected at main river stations for physical-chemical analyses (see Table 1-6) and at tributary and discharge stations for turbidity. Further details of sampling procedures are given below.

#### Main River Stations

To correlate with physical-chemical data collection locations at main river stations R-1 through R-23, in-situ parameters (see Table 1-6) were measured using a Hydrolab 6000D "Surveyor." In-situ measurements were taken at midstream five feet below the water surface or at mid-depth where the river was less than ten feet deep. Further physical measurements made in-situ were transparency (Secchi depth) and light transmission. The latter measurement was used to determine the euphotic zone, defined as the water column above the depth of 99% light extinction.

Analytical methods for physical-chemical and biological parameters, Middle Black Warrior and Tombigbee Rivers, July 1978 to October 1979. TABLE 2-1.

Water samples were collected at main river stations for laboratory analysis of the physical-chemical parameters listed in Table 1-6. Samples were collected five feet below the water surface or at mid-depth where the river was less than ten feet deep. A one-liter acrylic horizontal water sampler was used to collect the water from the desired depth.

In addition to the above data collection, in-situ measurements (via the Hydrolab) were taken to define any vertical physical-chemical stratification at the mid-stream point. Each month, beginning with Trip 3, a comparison was made between in-situ measurements at one foot below the surface and at three feet above the river bottom. If the field personnel observed an apparently significant variation in any of the in-situ parameters, an additional water sample for physical-chemical analysis was then drawn from three feet above the river bottom using a vacuum pump. (To preserve any anaerobic qualities, the sample was drawn into a nitrogen purged flask and was then carefully poured into a sample bottle and tightly capped.) When no apparently significant vertical stratification was observed, the lower depth was measured only for in-situ parameters.

Further observations on mixing and stratification were made three times during the study: October 1978, February 1979 and August 1979. During these months, in-situ parameters were measured at the one foot and near-bottom depths at three points along a horizontal transect. These points were chosen to include the littoral zone of each shore and the deepest point of the main river channel.

#### Cross Section Stations

At stations R-8 and R-22 the in-situ parameters were measured in a vertical profile at three or four points across the width of stream. This profile was either a top and bottom comparison or, if the comparison showed apparently significant stratification, the profile was completed to be a continuous record.

### Below a Lock

Station R-11, located in the tailrace of Warrior Lock, was monitored for in-situ parameters before and after operation (dewatering) of the lock. These measurements were made at five feet or at mid-depth if the depth was less than ten feet. Additionally, a 125 ml sample was collected at the same depth before and after dewatering and analyzed in the laboratory for turbidity.

### Tributary and Discharge Stations

Tributary stations T-1 through T-11 and Discharge stations D-1 through D-6 were also measured for in-situ (Hydrolab) parameters and turbidity at five feet or mid-depth where the depth was less than ten (10) feet. Measurements and samples were taken in the mouths of tributaries, as far upstream as necessary to eliminate the major influences of the river proper. Discharge samples were taken at the point where the discharge entered the river or the nearest accessible and affected point below the discharge.

# 2.1.1.2 Analyses

Analytical methodology for physical-chemical parameters are presented in Table 2-1. During the course of this study, it was

necessary to alter some of the procedures as they were specified in the contract at the initiation of the project. The changes, as a whole, are minor and are tabulated in Table 2-2. Slight method adjustments were made (sample volumes, pretreatment for interferences, etc.) in the analytical laboratory with increasing familiarity with the sample types. Where these adjustments were included in the analytical methodology as an adjunct to published methods, they do not appear in Table 2-2.

### 2.1.1.3 Quality Control

Laboratory analyses were monitored using a system of duplicate sample analyses, spiked sample analyses and analyses of "blind" check samples. The duplicate and spiked analyses were statistically evaluated for precision and accuracy by the Shewhart method (U.S. EPA, 1979).

Each duplicate and spiked analysis was performed by two methods -field splits and spikes and laboratory splits and spikes. One sample
was duplicated for each sampling day. Field duplicates were obtained
by splitting the grab sample into two containers which were plainly
labeled. Each field duplicate sample was analyzed for each required
parameter and the results were averaged for reporting. 50% of the
duplicate samples for heavy metals analyses were spiked with known
quantities of metals. Laboratory duplicates were performed at random
by the analyst for various parameters. These extra duplicate analyses
served as an independent check of the method and the analyst. Laboratory
spiked samples were routinely analyzed by the known addition method for
each applicable parameter (see Appendix B for the parameters analyzed
in this program).

Shewhart precision and accuracy charts were used to evaluate the validity of results obtained as described in EPA's "Handbook for Analytical Quality Control in Water and Wastewater Laboratories," (1972). These charts were maintained using results of duplicate and spike analyses. The quality control data was routinely consulted and checked by the analyst and the quality control co-ordinator. If any results were judged to be "out of control" according to the Shewhart charts, the analyses were repeated. If repetition was not possible, the results were not reported.

Calibration curves were calculated using a least-squares linear, regression to calculate the best-fit line for standards. Standards were prepared daily and run with each set of analyses.

#### 2.1.2 Sediment

#### 2.1.2.1 Sampling

Sediment samples for physical-chemical analysis were collected at each main river station twice during the study (Table 1-6). An epoxy-coated 9" x 9" Ponar dredge was used to collect one sediment sample from each of four equally spaced points across the river. This transect began and ended near each bank. The four samples were composited by mixing them in a large glass-lined box. After thorough mixing by stirring, aliquots for analysis were taken from the composite. The aliquots were preserved and stored according to methods given in Table 2-1.

2-7

Procedural changes in physical-chemical methods for Middle Black Warrior and Tombigbee Rivers, July 1978 through October 1979. Table 2-2.

PARAMETER METHODOLOGY	CARBON. DISSOLVED ORGANIC	COLOR, TRUE	TURBIDITY
METHOD ALTERED	Catalytic combustion, infrared analysis; EPA 1976, p. 237.	Visual comparison; Standard Methods 14th Ed., p. 64.	Field Turbidimeter
METHOD REQUIREMENT	Filter sample on-site.	Centrifuge sample prior to color determination to remove turbidity.	Determine turbidity in the field (in situ).
METHOD ALTERATION	Filter sample immedi- ately prior to anal- ysis.	Do not routinely centrifuge sample.	Determine turbidity in the laboratory within 24 hours of sample collection.
REASON	Field-filtered samples showed consistently higher levels of DOC than TOC. Samples filtered in the lab immediately prior to analysis did not.	Turbidity of samples normally very low and non-interfering.	Turbidity determination in situ impractical and not necessary for accurate and precise results.

# 2.1.2.2 Analysis

Hethods of sediment analysis for heavy metals and chlorinated hydrocarbons are given in Table 2-1. Final extract analysis for chlorinated hydrocarbons was made using a Varian gas chromatograph equipped with an electron capture detector.

The analytical procedure for oil and grease in sediment was initially a separatory funnel extraction utilizing Freon, with a gravimetric determination of the oil and grease thus extracted. This method proved to be impractical, due to formation of an extremely heavy emulsion, in which the two phases (sediment and Freon) were indistinguishable.

The alternative method, which was used for all sediment samples, involved a Soxhlet extraction using Freon in a continuous four-hour extraction process. This method also employs a gravimetric finish to determine the quantity of oil and grease extracted into the Freon. This method is a standard method frequently used for extraction of hydrocarbons from solid materials. Oil and grease recovery was obtained with a wet sample weight of 50 grams.

# 2.1.2.3 Quality Control

Duplicate and spiked duplicate sediment samples were analyzed for heavy metals, chlorinated hydrocarbons and for the physical-chemical parameters listed in Table 2-1. Duplicate samples were prepared in the laboratory by withdrawing two aliquots from the well-mixed composite samples. One station was duplicated each sampling day.

Sediment samples were spiked in the laboratory for each applicable parameter for each sampling day. To spike these samples, the known addition solution was added to an aliquot prior to ultrasonic treatment. The ultrasonic vibrations caused a thorough mixing. The intent was to expose the spike to the sample and check for loss into media.

The results of duplicate and spike analyses were subjected to the Shewhart procedure as given in Section 2.1.1.

### 2.1.3 Mollusk

### 2.1.3.1 Sampling

Numerous attempts were made to collect Corbicula of an age sufficient to analyze ( $\geq$  2 years). No collection effort yielded enough Corbicula at any given location to justify analysis and this segment was eliminated from the study.

#### 2.2 BIOLOGICAL

#### 2.2.1 Bacteriological

Bacteriological analyses were conducted at main river stations and at specified bacteriological stations (Tables 1-5 and 1-6 and Figures 1-2 and 1-3) during the June through September sampling periods.

These analyses consisted of surface water collections, membrane filtration, incubation and counting for total fecal coliform bacteria and total fecal streptococcus bacteria performed as described below. A ratio of fecal coliform to fecal streptococci was calculated for each station. All equipment used to handle and prepare samples was sterilized by autoclaving at 15 psi for 20 minutes prior to each sampling trip and maintained in closed containers, and sterile foil wrappers.

# 2.2.1.1 Sample Collection and Preparation

Bacteriological water samples were collected by submersing a presterilized, plastic, two-quart milk container to the depth of one foot and allowing it to fill to approximately one liter. Four aliquots (two 10 ml and two 100 ml) were immediately vacuum filtered through sterile Millipore 0.45 µm gridded membrane filter pads. Each pad was then washed in three-20 ml portions of sterile, distilled water. Occasionally, due to siltation or expected high bacteria posulations, 5 and 50 ml aliquots were filtered. After each filtration, the filter pad was placed on the appropriate media in prepared plastic petri plates. These plates were then held in ice chests at approximately 4°C for no longer than eight (8) hours before incubation began.

### 2.2.1.2 Media and Incubation

Total fecal coliforms were cultured on M-FC broth with 1:100 percent rosalic acid added (APHA, 1975). Fecal streptococci were cultured on KF streptococcus agar absorbed onto 48 mm diameter sterile filter paper pads (APHA, 1975).

Both types of samples were incubated in Millipore-brand aluminum block heat-sink type portable incubators capable of holding temperatures to  $\pm~0.2^{\circ}\text{C}$ . Fecal coliforms were incubated at  $44.5^{\circ}\text{C} \pm~0.2^{\circ}\text{C}$  for twenty-four (24) hours and fecal streptococci were incubated at  $35^{\circ}\text{C} \pm~0.2^{\circ}\text{C}$  for forty-eight (48) hours.

# 2.2.1.3 Counting and Calculations

After the appropriate incubation time, the plates were removed, visually inspected and the colonies counted. Fecal coliforms were defined on the M-FC rosalic acid media as blue greenish metallic appearing colonies. The fecal streptococci colonies cultured on the KF agar were reddish pink. All the observable colonies on each plate were counted and recorded. The number of colonies per 100 ml was then calculated for each bacterial type by taking the count form the pad that was within the proper range, as given in <u>Standard Methods</u>, 14th edition (page 943).

### 2.2.1.4 Quality Control

The bacteriological analysis was quality control (QC) monitored by the routine use of duplicates for at least 10% of the inoculations. Duplication involved splitting a water sample and performing two (2) separate analyses. The results of the two (2) acceptable duplicate samples were averaged for the reported result. An acceptable duplicate

was taken to be < 10% variation between the counted colonies. If this level of variation had ever been exceeded, and if physical differences in the plates (e.g. filter pad not contacting media in one plate) could not be seen, the results for the station would have been discarded.

# 2.2.2 Phytoplankton

### 2.2.2.1 Collection and Preservation

The collection of phytoplankton samples for identification and enumeration was performed at each main river station (Table 1-1 and Figures 1-2 and 1-3) during each sampling trip. A composite sample was prepared by mixing one liter grabs obtained with a PVC alphatype horizontal sampler at one meter intervals throughout the euphotic zone (Table 2-1). The depth of the euphotic zone was determined by measurement of the 1% light transmission depth with a submersible Montedero-Whitney photometer (see Section 2.1.1). A one liter aliquot of the well-mixed composite was then poured into a two quart jug and enough sodium tetraborate neutralized formaldehyde added to produce a 5% formalin preservation.

# 2.2.2.2 Counting and Calculations

Upon return to the laboratory, the samples were counted by the inverted microscope procedure of Utermohl (1958), with the exception of counting duration. Each sample was mixed by gentle inversion of the container at least 40 times and an aliquot poured into 50 ml combination tube-base plate settling chambers using an Utermohl cup. The actual size of the aliquot used varied due to siltation or algal density in the sample, but was normally 10, 25 or 50 ml.

An ideal sample was considered to have non-clumped, random distribution with the settled material only one layer (5-10m) thick. Early in the study, the ability of the equipment to produce random distribution was checked statistically using the chi-square method (Lund, et. al., 1958) and was found to be reliable (25 counts in 5 sets of 5 counts tested, Poisson's Law, p=0.05). Thus, according to the authors, a single count is sufficient to produce reliable estimates of phytoplankton numbers. Thus, after pouring, each tube was allowed to settle at least eighteen (18) hours and then used for algal identification and enumeration.

Phytoplankton counts were made using a Wild-Heerburg M40 inverted biological microscope equipped with 4X, 10X, 43X and 100X planachromatic Floutar objectives and 10X wide field compensating eye-pieces fitted with a European style 12x12  $_{\rm J}$  id (41,616  $_{\rm L}$ m² at 430X). The settling chambers were examined in horizontal strips along randomly spaced vertical axes at 430X. The identification and enumeration of phytoplankton along these strips was continued until 300 plants had been observed. For colonial, coenobic or filamentous forms, cell counts (or estimates) were made for each plant. Algae were consistently identified to genus and routine identification to species was made where feasible. The two dominant algae (by cell density) were always identified or ralated to species. Characterless or otherwise unidentifiable volvocine and coccoid green algae were lumped together as "unknown

chlorophytes"; obscured, minute or otherwise unidentifiable Pennales were lumped together as "other pennate diatoms".

Calculation of the reporting value was made by the following formula:

cells/liter = N x 
$$\frac{TA}{AE}$$
 x  $\frac{1000}{AV}$ 

where:

N = number of cells observed while counting

TA = total area of campber (500 mm<sup>2</sup>)

AE = area examined (mm<sup>2</sup>) AV = aliquot volume (ml)

The summarized values for major divisions and classes were then entered on the EPA STORET system.

References used for identification of phytoplankton were Cocke (1967), Drouet and Daily (1956), Drouet (1968, 1973, and 1978), Patrick and Reimer (1966 and 1975), Prescott (1978), Prescott, Croasdale and Vinyard (1972, 1975, and 1977), Smith (1920, 1921 and 1950), Vinyard (1974), Weber (1966) and Whitford and Schumacher (1973).

### 2.2.2.3 Quality Control

Phytoplankton identifications and enumerations wer QC monitored by two (2) methods. Split sample aliquots were sent to the COE for outside expert verification. In-house split sample aliquots were occasionally analyzed to determine consistency of the sample handling and analysis procedures. When a new phycologist was added (may 1979), all aspects of the procedure including sample preparation, identifications, counting method and calculations were compared on a one-to-one duplication basis until uniform results were achieved.

#### 2.2.3 Zooplankton

#### 2.2.3.1 Collection and Preservation

Collections for zooplankton identification and enumeration were made during each sampling period (Table 1-1) at each main river station (Table 1-1 and Figures 1-2 and 1-3). Sampling procedures used a metered net and laboratory analysis was accomplished by direct microscopical examination of the zooplankton.

Field collections for zooplankton were made using a 0.5 m diameter, 80 µm mesh Wisconsin style net. A flow meter was suspended at the upper collar of this net and was held in place while lowering the net by a device designed after that of Dycus and Wade (1977). The net was closed, lowered to within 8 to 10 feet of the bottom and the meter released by a messenger weight. The net was then vertically towed to the surface at a rate no greater than 1 m/sec. The final meter reading was recorded for calculation of the volume of water passed through the net. (This calculation was based on meter readings obtained by towing the net from known depths and thus known volumes in a swimming pool. The net-meter system was calibrated several times

during the study to correct occluding of the mesh openings). The outside of the net was then rinsed to wash all organisms into the collecting bucket from which they were transferred to a plastic 250 ml sample bottle. A few drops of borax buffered formaldehyde was added to produce a 5% formalin solution.

Occasionally, net clogging due to silt or abundance of organisms was encountered. At these times, the net was towed to the estimated point at which clogging would begin, closed, pulled to the surface and rinsed as described above. The meter reading was recorded, the net reclosed, relowered to the ending depth from the previous tow, triggered and the steps repeated until the column had been sampled.

### 2.2.3.2 Counting and Calculation

Upon return to the laboratory, samples were well-mixed by gentle inversion and poured into a graduated cylinder. A one ml aliquot was removed with a Henson-Stempel pipet and carefully injected into a Sedgwick-Rafter counting cell. This aliquot was allowed to settle for a few minutes. Counting was done on a Baush-Lomb compound microscope equipped with 4X, 10X and 20X objectives and 10X widefield eyepieces. Horizontal strip counts were used, beginning in the upper left corner and proceeding until 300 organisms were encountered. If this many animals had not been observed in the examination of five (5) entire counting chambers, the procedure was stopped. Identification of organisms was routinely made to genera and specific epithets were provided for the two dominant genera.

Reporting values were calculated by the following formula:

organisms/liter = 
$$\frac{SV}{VE} \times N$$

where:

N = number of organisms counted in chamber SV = sample volume measured in cylinder (ml)

VE = volume examined in chamber (ml)

TV = total volume passed through the net (1)

This number was reported as calculated, unless <0.05, in which case it was normally reported as <1. Group summaries for each month were entered in the EPA STORET system.

References used for the identification of zooplankton organisms were Eddy and Hodson (1961), Edmondson (1959), Jahn (1949), Kudo (1946) and Pennak (1953, 1978).

# 2.2.3.3 Quality Control

Zooplankton identifications and enumerations were 3C monitored in tow (2) ways. Split sample aliquots were sent to the COE for verification. In-house split sample aliquots were occasionally analyzed to determine consistency of the sample handling and analysis procedures. When a new biologist was added for zooplankton analysis (May 1979) all procedures, including sample preparation, identifications, counting method and calculations were compared on a one-to-one basis until uniform results were achieved.

### 2.2.4 Macroinvertebrates

Macroinvertebrates were collected at selected stations during each sampling period by either Ponar dredge or multiple plate sampling (Table 1-5). The collection and preservation methods for the two types of samplers are given below, followed by a generalized discussion of counting and calculation.

### 2.2.4.1 Collection and Preservation

#### Ponar

Benthic macroinvertebrate samples were collected by the use of a 9" x 9" weighted Ponar dredge. Three different dredges were used during this study, each with slightly different dimensions, thus providing varying areal multipliers. A single dredge sample was pulled from near the right and left banks and at midstream of each station. These were individually field washed through U.S. Standard No. 30 mesh screens and preserved with enough formalin to produce a final 10 percent concentration. The samples were stored in labeled plastic containers for transport.

A final washing was made in the laboratory by using a concentrated saline flotation (Weber, 1973) to remove the invertebrates and detritus from the bulk sediment. This material was represerved in rose bengal stained 10 percent formalin solution until counted.

# Multiple Plate Samplers

The multiple plates used during this study were the modified Hester-Dendy "Jumbo" type described by Weber (1973) cut from 1/4" thick double tempered Masonite. The final total area of the sampler was  $0.14~\rm m^2$ . The samplers were generally suspended to a depth of four feet from buoys (except Station 4 where tree branches were used) by the use of nylon rope or steel aircraft cable.

After a six week exposure period, the multiple plate samplers were retrieved by gently raising the sampler to the surface, lowering a No. 30 mesh bucket under it and then lifting the plates out of the water. The sampler and any invertebrates in the mesh-bottomed bucket were placed on ice and transported to the laboratory where they were further processed within 24 hours.

Final processing involved disassembling the sampler and gently scraping the attached invertebrates onto a No. 30 mesh screen. The samples were washed clean of all possible detritus and rinsed into plastic containers with enough rose bengal stained formalin to make a 10 percent preservation.

# 2.2.4.2 Counting

For both dredge and multiple plate samplers, the procedures for counting were identical. The samples from the final storage containers were rinsed free of formalin, placed in white enamel trays and the organisms separated from the detritus. A 2X illuminated magnifier or 7X magnification with a dissecting microscope was used to aid sorting. The sorted organisms from dredge samples were placed in

water and held at  $4^{\circ}$ C until weighed. The samples collected by the multiple plate method were not weighed.

Taxonomic separation and enumeration was performed using a Nikon 0.8X - 4X dissecting microscope and 10X eyepieces. Diopters and 15X eyepieces gave the possibility of up to 120X total magnification for aid in identification. Organisms were usually identified to genera unless monospecific or otherwise easily identifiable to species. Nematodes were identified only to class and Oligochaeta to family. Chironomids were mounted in Hoyer's mounting medium and identified with the compound microscope. Other unwieldy classes were taken to the lowest toxan practicable.

References used in laboratory identification were Beck (1976), Brinkhurst (1971), Brown (1976), Ferris, Ferris and Tjepkema (1973), Mason (1973), Merritt and Cummins (1978), Needham and Westfall (1954), Parrish (1975), Roback (1976, 1977, 1978), Usinger (1956) and Edmundson (1959)

#### 2.2.4.3 Biomass

The organisms from the dredge samples were blotted dry and weighed to the nearest 0.1 mg. Corbicula greater than 0.5 cm valvar height in these samples were not all weighed, but rather an average wet weight of the meat was applied by 0.5 cm diameter classes. The average weights for these classes were 0.5 - 1.0 cm, 4.1 mg; 1.0 - 1.5 cm, 95 mg; 1.5 - 2.0 cm (none collected), 2.0 - 2.5 cm, 557 mg; 2.5 - 3.0 cm, 1.3 g; 3.0 - 3.5 cm, 2.2 g; 2.5 - 4.0 cm, 2.7 g; 4.0 - 4.5 cm, 3.4 g; 4.5 - 5.0 cm and 5.1 g.

# 2.2.4.4 Calculations and Indices

For each Ponar and multiple plate sample, the number of organisms per square meter was calculated by simply applying the appropriate multiplier to produce the number on a total square meter. For example, the multiple plate samples were 0.14  $\rm m^2$ , the multipler is 7.1. As previously stated, three different Ponar dredges were used, but the individual multipliers were obtained in the same manner.

Data evaluation for Ponar samples included the calculation of a diversity index for each station. The machine formula of Lloyd, Zar and Karr (1968) was used to provide the Shannon-Weaver diversity  $(\bar{d})$  measured as follows:

$$d = C/N (N log_{10} N - \Sigma n_i log_{10} n_i)$$

where:

C = 3.321928

N = total number of individuals

 $n_i = total number of individuals in the i<sup>th</sup> taxa$ 

Evenness, an index of distribution of the numbers among the species, was calculated by the following formula (Weber, 1973):

 $\frac{\overline{d}}{\ln N}$ 

These two indices were calculated from totals for each station, i.e., summations of taxa and numbers from right bank, mid-channel and left bank.

The summary data from Ponar collections was entered into the EPA STORET system.

# 2.2.4.5 Quality Control

Macroinvertebrate identifications and enumerations were QC monitored by a system of cross-checks and repeat counts among the participating biologists, within each set of samples a few would be recounted and identifications compared for agreement. Disagreement was resolved and a further sample checked with agreement was reached. The separation step was monitored by checking the material remaining after each flotation for obvious organisms. To insure the validity of the taxonomy used, representative organisms were sent to the COE.

# 2.2.5 Aquatic Macrophytes

Macrophytic vegetation includes nonvascular and vascular plants associated with the impoundment substrate or shoreline. General categories for macrophytes include those plants that are free-floating or are attached by roots and are either completely underwater (submerged) or partially above water (emergent).

Observations of macrophytes were performed during two trips (Table 1-6). The primary method of detection was by direct examination of shorelines, embayments, creeks and sloughs and the shallower areas of the reservoir proper. The investigator made field notes and collections indicating species, areas of growth and location. For various species, a permanent botanical record was made by herbarium-type mounting of plants.

Reporting was done by compilations of species lists for the reservoir, distribution and abundance maps giving locations and approximate areal extent for the dominant plants.

References used for identification of the plants seen and collected were Radford, Ahles and Bell (1968) and Small (1933).

# 2.2.6 Other Parameters

# 2.2.6.1 Algal Growth Potential (AGP) Test

# <u>Sampling</u>

Water samples were collected for AGP tests from selected main river stations (see Table 1-5) during three sampling trips (see Table 1-6). The sample was obtained by compositing individual grabs taken at one meter intervals throughout the euphotic zone (see Section 2.1.1). Several liters of the well-mixed composite were transferred to autoclavable Nalgene bottles and transported on ice in sealed the chests.

# <u>Analysis</u>

Upon receipt at the laboratory, a portion of each iced sample was removed and set aside for chemical analyses. The remainder was autoclaved at 15 psi and  $121^{\circ}$ C for 30 minutes. After autoclaving, the sample was filtered using sterile techniques. The filtered water was aerated with sterile (0.45 µm filtered) air to restore lost  $CO_2$  balance. Chemical analyses were performed on the previously set aside sample and the autoclaved, aerated sample for the following parameters: total Kjeldahl nitrogen, nitrate and nitrite, ammonia, total phosphorus, dissolved orthophospate, conductivity and pH using the procedures described in Section 2.1.1. The water remaining from the autoclave treatment was used for AGP test.

# AGP Test Procedure

Methodologies used for setting up and performing the AGP test were taken from the USEPA publications Algal Assay Procedures: Bottle Test (1971) and The Selenastrum Capricornutum Printz Algal Assay Bottle Test (1978) and was primarily designed after procedures in the 1971 report. These documents should be consulted for amplification of details of this procedure such as glassware preparation.

Each of the water samples for each station was used to prepare eight test flasks in triplicate, which received the following nutrient "spikes":

In 25 ml of sample water, in a 125 ml Erlenmeyer flask,

Test I - Lake water sample

Test II - Lake water sample + 0.05 mg P/l as K<sub>2</sub>PO<sub>4</sub>

Test III - Lake water + 1.00 mg N/l as NaNO<sub>3</sub>

Test IV - Lake water + 0.05 mg P/l + 1.00 mg N/l

Test V - Lake water + 1.00 mg Na<sub>2</sub>EDTA/1

Test VI - Lake water + 0.05 mg P/1 + 1.00 mg Na<sub>2</sub>EDTA/1

Test VII - Lake water + 1.00 mg P/l + 1.00 mg Na<sub>2</sub>EDTA/l

Test VIII - Lake water + 0.05 mg P/1 + 1.00 mg N/1 +

1.00 mg Na<sub>2</sub>EDTA/1

The nutrient spikes were introduced by 0.25 ml injections of appropriately concentrated stock media to the 25 ml of sample water, thereby providing negligible volumetric difference between the flasks.

Into each of the flasks an inoculum of approximately 5,000 cells of the test alga (Selenastrum capricornutum Printz) was introduced by sterile pipets. The alga was obtained from a laboratory stock culture maintained from original material provided by the Corvallis office, USEPA. The inoculate culture was fourteen days old when it was inoculated into the test flasks.

The flasks were placed onto a shaker table, prepared according to USEPA (1978), in a 10' x 10' controlled environment chamber. The shaker table was agitated approximately 85 oscillations per minute; the temperature was  $75^{\circ}F + 2^{\circ}F$ . Illumination was provided by a bank of cool white flourescent lights positioned to provide 4,400 lumens at the table surface. The flasks were left at these conditions for 12 days when a 5 ml sample was drawn off for standing crop estimation;

at 14 days the test was halted, and the entire sample was preserved with the addition of enough formalin to make a 5 percent preservative solution. These preserved samples were used for final 14 day standing crop estimation.

# Standing Crop Estimation

A standard Neubauer hemacytometer was used to estimate the number of algal cells produced per milliliter of the culture media. A 0.1 ml drop was placed on each grid of the hemacytometer with a blood pipet and a total of 200 of the smallest squares were counted on each. If the two counts did not agree to within 10 percent, a third was counted and the disagreeing count rejected.

The hemacytometer count was converted to cells/milliliter by the following formula (adapted from Hauser Scientific, 1974):

$$cells/ml = \frac{N \times DF \times CF}{A}$$

where:

N = number of cells counted

DF = dilution factor (DF = 1, no dilution)

CF = correction factor for volumes (CF =  $4 \times 10^6$ 

A = number of squares counted  $(4 \times 10^2)$ 

After one test, an attempt was made to correlate cell numbers to weight using the 0.45  $\mu m$  membrane filter technique (USEPA, 1971). This procedure was abandoned after this single trial due to non-reproducible results.

# Chlorophyll a, b and c

Chlorophyll samples were collected at main river stations during each sampling period (see Figures 1-2 and 1-3 and Table 1-1). The samples were obtained by compositing individual grabs taken at one meter intervals throughout the euphotic zone (see Section 2.1.1). Triplicate aliquots of 300 - 1,000 ml were withdrawn from the well-mixed composite and filtered through glass fiber filter pads at approximately one-half atmosphere (8 psi). The filter pads were placed in individually labeled plastic bags and stored on ice and, upon return to the laboratory, were stored at -4°C until analyzed.

Chlorophyll was extracted and analyzed by the spectrophotometric method as detailed in the 14th edition of <u>Standard Methods</u> (APHA, 1975). Concentrations of the pigments were determined by the trichromatic equations and pheophytin corrected chlorophyll  $\alpha$  values (APHA, 1975).

# Adenosine Triphosophate (ATP)

Samples for ATP analysis were collected at each main river station during each sampling period (see Figures 1-2 and 1-3 and Table 1-1). The samples were obtained by compositing individual grabs taken at one meter throughout the exphotic zone (see Section

2.1.1). Triplicate aliquots were filtered through glass fiber filter pads at approximately one-half atmosphere (8 psi). The ATP was extracted in the field and the extract frozen until analyzed.

Analytical methodology followed that of ASTM method 0:-031077-16 (ASTM, 1978).

# Qualisy Control for Chlorophyll and Adenosine Triphosphate analyses

These quantitative indicator analyses were not performed using Shewhart QC methods. Rather, triplicate analyses were performed in each case and the results averaged to give the final answer. This arrangement was satisfactory in that it aided in and eliminated the variability inherent in the collection of biological samples. Additionally, ATP analyses were monitored by spiking samples with known concentrations of ATP and checking instrument response. Chlorophyll  $\alpha$  was checked using EPA-supplied knowns. All independent checks produced answers indicating reliable analyses.

#### **RESULTS**

#### 3.1 PHYSICAL-CHEMICAL

The results of physical-chemical measurements and analyses are presented in summarized form in this section. Tabulations of all raw data can be found in the Appendices.

The summaries presented in this section have been subdivided in two ways. The parameters have been grouped by related categories, i.e., in-situ measurements, major ions and related parameters, nutrients, heavy metals and microbiological parameters. These parameter groups have then been tabulated by river sections as presented in Section 1.0 of this report (see Tables 1-1, 1-2, 1-3 and Figures 1-2, 1-3). These two subdivisions allow for an assessment of the means and ranges of the parameters between sections of the study area with markedly different concentrations and trends of many investigated parameters.

To adequately distinguish the variation in water quality between the river basins, a further subdivision has been added to the segments given in Section 1. This secondary segmentation considers the Black Warrior River above Warrior Lock and Dam (Stations R-1 through R-9, hereinafter referred to as Warrior Lake) and below Warrior Lock and Dam (Stations R-10 through R-16, hereinafter referred to as the Lower Black Warrior River). The remaining stream segments are the Tombigbee River (R-17 through R-21) and Demopolis Lake (R-22 through R-23). The tributary (T) and discharge (D) stations are included in the appropriate river reach for the tabulation of in-situ parameters. These four river section designations will be utilized for results presented in Section 3.1.

#### 3.1.1 Water

All physical-chemical and associated water quality parameters investigated during this study are summarized in this section. The following tables present the means and ranges for the parameters. The individual means were calculated from the total number of concentrations for a station from all sampling trips. Grand means for the river section are given at the right-hand side of each table.

#### 3.1.1.1 In-Situ and Associated Parameters

#### Main River Stations

Tables 3-1 through 3-4 show the means and ranges for in-situ and associated parameters for all main river stations. The tributary and discharge stations are included in downstream order to indicate any water quality changes contributed by these sources, but do not figure in the grand mean.

Water Temperature. Mean water temperatures were approximately 23-24°C for all river stations. The lowest mean temperature was 26.1°C at station R-16 (Table 3-2). The lowest monthly water

temperatures were recorded in February 1979 and ranged from 7.5°C at R-10 to 13.0°C at R-21 (Table A-5). The highest monthly temperatures occurred during August 1979, with a range of 28.0°C (recorded at several Warrior Lake stations) to 34.0°C recorded in the late afternoon at station R-14 (Table A-9). Temperatures greater than and equal to 27.0°C were recorded during August and September 1978 and June, July and August 1979 (see Appendix A).

Warrior Lake experienced the lowest mean temperature of the four river sections (23.2°C). The remaining river sections were approximately 1°C warmer on the average, with the lower Black Warrior River having the highest average, 24.4°C (Tables 3-1 through 3-4).

Euphotic Zone (Light Transmittance). The depth of the euphotic zone, which is defined as the depth of 99% incident light extinction, showed extensive variation between river sections and between sampling trips. The greatest mean euphotic zone was 9.0 feet at R-1 (Table 3-2); the lowest average depth of the euphotic zone was 3.7 feet at R-18 on the Tombigbee River (Table 3-3). The lowest monthly light transmittances were recorded in May 1979 (Table A-6); the greatest monthly values occurred in October 1978 (Table A-3). The single deepest euphotic zone was 15 feet (stations R-1 and R-13, October 1978, see Table A-3), the single shallowest was 0.2 feet (R-19, May 1979, see Table A-6).

The average depth of the euphotic zone was essentially equal in Warrior Lake and the Lower Black Warrior River (7.1 feet and 7.2 feet, respectively; see Tables 3-1 and 3-2). Demopolis Lake had only a slightly shallower euphotic zone (6.9 feet, see Table 3-4). The Tombigbee River was distinctly less transmissive with the average depth of the euphotic zone being 4.7 feet (Table 3-3), approximately 40% shallower than the other sections.

These sectional comparisons mask one overall trend in the Black Warrior River: Warrior Lake consistently had the greatest light transmittances with the deepest generally occurring at R-1. There was then a downstream decline in light transmittance between R-2 and R-6 (from an average of 9.0 feet at R-1 to 5.8 feet at R-6, see Table 3-1). The euphotic zone then gradually deepened to an average of 7.8 feet at R-9 (Table 3-1). The Lower Black Warrior River showed a similar trend with the station below Warrior Lock and Dam having a shallower euphotic zone than those stations closer to Demopolis Lake (e.g., the mean light transmittance at R-10 was 6.2 feet and at R-16 the mean was 7.5 feet; see Table 3-2). This trend is noticeable within most monthly data collections (see Appendix A).

Turbidity. Turbidity values evidenced large variations between both stations and dates. The lowest average turbidity, 8 FTU, was at R-19 (Table 3-3). The lowest monthly turbidities were recorded during October 1978 (Table A-3); the highest were during February 1979 (Table A-5). The minimum turbidity for the study was 2 FTU which occurred at R-18 and R-19 in August 1978 (Table A-1) and several other Black Warrior River stations in October 1978 (Table A-3). The maximum turbidity for the study was 195 FTU which occurred at R-17 in February 197) (Table A-5).

The major trend among the river sections was increasing turbidity downstream. Warrior Lake had the lowest mean turbidity, 14 FTU (Table 3-1). The Lower Black Warrior River increased to 22 FTU (Table 3-2). The Tombigbee River yielded the highest average turbidity, 41 FTU (Table 3-3). Demopolis Lake had an average of 24 FTU (Table 3-4). Thus, the Tombigbee River had 40% - 55% greater turbidity than the other river sections.

Color. Color is measured in plantinum-cobalt color units. In this section the numerical values all refer to Pt-Co units.

Color values varied widely between sampling dates, river stations and river sections. The station with lowest average color, 12, was R-1 (Table 3-1); the highest was 45 at R-21 (Table 3-3). The minimum color value during the study was 5 (R-1 in July 1979, Table A-8, and R-5 in Ottober 1979, Table A-10). The maximum color, 95, occurred at R-20 in October 1979 (Table A-10).

Similar to turbidity, color generally increased downstream on the Black Warrior River, rising from 14 in Warrior Lake to 16 in the Lower Black Warrior River. The Tombigbee River color levels averaged over 100% higher than the Black Warrior River with an average color value of 37. Demopolis Lake dropped only slightly lower than the Tombigbee River on the average (31) and was twice the color intensity of the Black Warrior River.

Transparency. The transparency, as measured by Secchi disc, evidenced much less variation than turbidity and light transmittance. The highest average transparency was 1.1 meters observed at R-1 (Table 3-1) and the lowest average transparency was 0.3 meters observed at R-19 (Table 3-3). The most transparent conditions were observed in October 1978 (Table A-3); the least in February 1979 (Table A-5). The single highest transparency was 2.2 meters (R-1, July 1979, Tables 3-1 and A-8). The minimum transparency recorded was 0.1 meters. This value was observed at several Tombigbee River Stations in February and May 1979 (Tables 3-3, A-5 and A-6).

Transparency generally decreased downstream, as compared between the river sections. However, the variation between the sections was not as distinct as it was for the other clarity measurements. Warrior Lake had the greatest transparency, 0.8 meters (Table 3-1) with a decrease to a 0.7 meters in the Lower Black Warrior River (Table 3-2) and 0.6 meters in Lake Demopolis (Table 3-4). The Tombigbee River, while not extremely less transparent, had the lowest average, 0.5 meters (Table 3-3). These trends support the general trend of decreasing clarity downstream on the Black Warrior River, with the Tombigbee River contributing water of a much lower clarity to Demopolis Lake which maintains a clarity influenced by both rivers.

Oxidation-Reduction Potential. The measurement of oxidation-reduction potential (ORP) produced very little variation between samplings, but larger variations between river stations and river sections. The greatest mean ORP was 410 mV at R-7 through R-10 (Tables 3-1 and 3-2). The lowest mean ORP was 360 mV at R-20 (Table 3-3). The highest ORP was 560 mV which occurred at R-6 during late August 1979 (Table A-9); the lowest was 230 mV at R-6, in December 1978 (Table A-4). The lowest monthly ORP values were recorded in December

1979 (Table A-4). The highest monthly ORP's were recorded in late August 1979 (Table A-9).

Between the river sections, only the Tombigbee River varied from the grand mean of approximately 400 mV. Warrior Lake and the Lower Black Warrior River averaged approximately 400 mV for the entire study (Tables 3-1 and 3-2). Demopolis Lake had an average of 390mV (Table 3-4). The Tombigbee River averaged only 6% lower, 375 mV (Table 3-3). These results demonstrate relatively equal ORP values for the entire study area averaged over the entire study period with the Tombigbee River having slightly lower ORP values (see monthly data in Appendix A).

Specific Conductance. As with ORP (see Table 3-1 through 3-4) variations were not extreme between river stations. The greatest variation occurred between dates. The highest specific conductance (conductivity) observed during the study was 215  $\mu$ mhos/cm recorded at R-4 in October 1978 (Table A-3) and at R-7 through R-12 in October 1979 (Table A-10). The lowest conductivity was 35  $\mu$ mhos/cm at R-20, August, 1978 (Table A-2).

Between the river sections, the Tombigbee River averaged a 30% lower conductivity than either Black Warrior River section or Demopolis Lake. The Black Warrior River averaged 180  $\mu$ mhos/cm and 170  $\mu$ mhos/cm for Warrior Lake and the Lower Black Warrior River, respectively (Tables 3-1 and 3-2). Demopolis Lake averaged slightly lower at 158  $\mu$ mhos (Table 3-4). The Tombigbee River was consistently lower (Appendix A) with an average of 125  $\mu$ mhos/cm (Table 3-3).

Dissolved Oxygen. Dissolved oxygen (DO) concentrations varied considerably by month, station and river section. Station R-5 had the highest everage DO, 9.3 mg/l (Table 3-1). The lowest average DO was 7.5 mg/l at R-19 and R-21 (Table 3-3). The single highest DO was 11.8 mg/l observed at R-10 during an early morning (0937 hours) measurement in February 1979 (Table A-5). The lowest DO was 5.2 mg/l recorded at R-19 and R-20 in October 1978 (Table A-3). It should be noted that DO values almost as low were observed between stations R-19 and R-22 in August and October 1979 (Table A-9 and A-10, respectively).

Warrior Lake and the Lower Black Warrior River had equal mean DO levels, 8.5 mg/l (Tables 3-1 and 3-2). The Tombigbee River showed only a 9% reduction in average DO with 7.8 mg/l (Table 3-3). Demopolis Lake, with an average of 8.0 mg/l (Table 3-4), fell between the levels of the two rivers. This trend is evidenced in the monthly data collections (Appendix A) which show a general decrease in DO values in the Tombigbee River as compared to the Black Warrior River and Demopolis Lake.

<u>pH.</u> The pH showed the least variation of any of the in-situ parameters. The approximate median range was  $6.8-7.8\,$  S.U. for all river sections. The minimum average pH for this study was  $7.0\,$  S.U., recorded at R-1 (Table 3-1); the maximum was  $7.8\,$  S.U. at R-19 and R-20 (Table 3-5). The most basic pH value recorded during the study was  $8.9\,$  S.U. (Station R-20 during early and late August 1978, Tables A-1 and A-2). The most acidic pH measurement was  $6.1\,$  S.U. taken at R-5 (July 1978, Table A-1).

As with dissolved oxygen, grand average pH values were equal in the two Black Warrior River segments (7.2, Tables 3-1 and 3-2). The Tombigbee River was generally more basic, having an average pH of 7.6 S.U. (Table 3-3). Demopolis Lake pH was 7.3 S.U., on the average (Table 3-4). These trends are generally observable in the monthly data collections (see Appendix A).

# Tributary and Discharge Stations

Results of in-situ measurements made at tributary and discharge stations during monthly data collections are found in Appendix C. Summaries of this data are found in Tables 3-1 through 3-4. The tributaries and discharges are listed as they occur between the river stations in each section. No attempt was made to calculate grand average of the tributaries in each river section due to the variations in the quality of the different influents.

Because of the lack of consistent trends in the river section, no presentation is made in this section regarding the effects of the tributaries and discharges on the rivers. The following results will therefore separate the results of the tributary and discharge measurements and the water quality impacts will be discussed in Section 4 of this report.

The following summary is presented as an aid to reading the following section. The reader should refer to Table 1-2 for more details on station locations.

D-3	APCO pond discharge	D-6	Borden Chemical Co.

<u>Water Temperature</u>. The general trend for tributary stream temperatures refeleted the main river station temperature variations with a maximum average variation of approximately  $3^{\circ}$ C. The lowest average temperature was  $20.7^{\circ}$ C at T-2 (Table 3-1); the highest average was  $24.3^{\circ}$ C at T-10 (Table 3-2). The lowest temperature recorded was  $6.5^{\circ}$ C at T-2 and T-3 in December 1978 (Table C-4). The highest tributary stream temperature was  $31.0^{\circ}$ C recorded at T-10 in July 1979 (Table C-8).

Discharge stations had approximately the same range of variation from the river mean temperatures as did the tributary stations. D-2 had the highest average temperature,  $27.1^{\circ}$ C (Table 3-1). The lowest average discharge temperature was  $23.4^{\circ}$ C at D-5 (Table 3-3). The highest temperature recorded at a discharge station was  $36.0^{\circ}$ C at

D-2 in July and August 1979 (Tables C-8 and C-9); the lowest was  $9.5^{\circ}$ C in December 1978 at D-5 and D-6 (Table C-4) and in February 1979 at D-3 (Table C-5).

Turbidity. Turbidity was the only measurement of clarity made at the tributary and discharge stations. T-11 had the highest average turbidity, 64 FTU (Table 3-3), of all tributary stations. The lowest average turbidity was 11 FTU, obtained at T-5 (Table 3-1). The single highest turbidity was 158 FTU, recorded at T-11 in May 1979 (Table C-6). The minimum turbidity was 1.7 FTU recorded at T-2 in August 1978 (Table C-2).

Discharge station average turbidities were generally lower than or equal to the average turbidities for the river sections. The lowest average turbidity was 14 FTU obtained at D-2 (Table 3-2), the highest average was 45 FTU, obtained at D-4 (Table 3-3). The single highest turbidity was 140 FTU, recorded at D-4 in February 1979 (Table C-5). D-3 had the lowest single turbidity, 1 FTU, recorded in July 1978 (Table C-1).

Oxidation-Reduction Potential. Oxidation reduction potential (ORP) values from tributaries showed no consistent trend in comparison to average river ORP measurements. The highest average tributary ORP was 398 mV at T-5 (Table 3-1). The lowest mean ORP for tributary stations was 327 mV, obtained at T-10 (Table 3-2). The maximum ORP value obtained for tributaries was 560 mV at T-5 in August 1979 (Table C-9); the minimum was 90 mV at T-4 in August 1978 (Table C-2).

Discharge station ORP values were consistently lower than the receiving river waters. D-1 and D-2 had the highest average ORP, 380 mV (Table 3-1 and 3-2, respectively). The lowest average CRP was 335 mV, obtained at D-4 (Table 3-3). The maximum ORP recorded for a discharge station was 470 mV (D-3, August 1979, Table C-9). The minimum ORP was 180 mV, recorded at D-3 during December 1978 (Table C-4).

Specific Conductance. Specific conductance had the widest ranges of any in-situ parameter measured at tributary or discharge stations. The lowest average conductivity reading at a tributary was 50  $\mu$ mhos/cm, obtained at T-4 (Table 3-1); the highest was 233  $\mu$ mhos/cm at T-10. The maximum conductivity recorded was 410  $\mu$ mhos/cm at T-7 in August 1978 (Table C-1). The minimum recorded conductivity for a tributary station was 30 mV (T-4 and T-5, December 1978, Table C-4).

The discharge stations generally had average specific conductivity values higher than the receiving river waters. The greatest average discharge conductivity was obtained at D-6, 583  $\mu mhos/cm$  (Table 3-4). The smallest average specific conductance was 118  $\mu mhos/cm$  which was obtained at D-4 (Table C-3). The minimum discharge conductivity was also recorded at D-4, 30  $\mu mhos/cm$  in August 1978 (Table C-1). The maximum recorded conductivity was at D-6, 1900  $\mu mhos/cm$  in October 1979 (Table C-10).

Dissolved Oxygen. Tributary and discharge stations were generally  $\pm 1.0~mg/1~cf$  the receiving river water dissolved oxygen (DO) concentrations. The tributaries with the highest average DO concentrations were T-2 and T-10 with  $\Omega$  mg/l (Tables 3-1 and 3-2). The lowest average DO

was 7.1 mg/l, obtained at T-4 (Table 3-1). T-9 had the lowest single DO level, 3.8 mg/l recorded in July 1978 (Table C-1). The highest DO, 14.4 mg/l was recorded at T-12 in June 1979 (Table C-7).

Discharge station D-1 had the highest average DO, 8.6 mg/l (Table 3-1). The lowest average DO was 7.8 mg/l obtained at D-6 (Table 3-4). The lowest monthly discharge station DO was 4.6 mg/l, recorded at D-5 (August 1978, Table C-1). The highest recorded discharge DO was 13.2 mg/l at D-5 (July 1979, Table C-8).

pH. The average pH values at all tributary and discharge stations were circumneutral  $(7.0 \pm 1.5 \text{ S.U.})$  The highest average pH was 8.3 S.U. at T-10 (Table 3-2); the lowest pH, 6.5 S.U., recorded at T-7 in February 1979 (Table C-5). The most basic single reading was 9.1 S.U. at T-10 (July 1978, Table C-1).

Discharge station pH values were not as varied as those obtained from the tributary stations. The highest average discharge pH was 7.8 S.U., obtained at D-5 (Table 3-3). The lowest average pH was 6.5 S.U., obtained at D-3 (Table 3-2). The most acidic station was D-3, with a pH of 5.1 S.U. in February 1979 (Table C-5). D-5 had the most basic pH reading, 8.8 S.U., in July 1979 (Table C-8).

# 3.1.1.2 Stratification and Mixing Studies

During the course of this study, three related data sets were obtained: Top and Bottom Comparison of In-Situ Parameters (see Appendix D), In-Situ Parameters Measured at Vertical Cross Section Stations R-8 and R-22 (see Appendix E) and Extensive Mixing Studies (see Appendix F). All three data collections involved making measurements of in-situ parameters in vertical profile along points of horizontal transects. The Top and Bottom Comparisons were begun in October 1978, the Vertical Cross Sections at R-8 and R-22 in July 1978 and Extensive Mixing Studies were done on the dates noted in 3.1.1.1.

# Stratification at Main River Stations

The results of these studies indicate very little stratification of the Black Warrior or Tombigbee Rivers. Table 3-5 provides a summary of noticeable stratification in the form of changes in temperature and dissolved oxygen (DO) from surface to just above the river bottom. The most important observation to be made from Table 3-5 is that although temperature and DO do show some minor stratification at certain times, the overall loss of oxygen or temperature change is never severe. As shown in Appendices D and E, the depletion of DO to a level near O mg/l was never observed. Indeed the lowest DO recorded during the study was 4.2 mg/l at 15 meters (R-22, August 1978. Table E-4). Thus, stratification studies generally showed minor and gradual variation in surface versus bottom water quality parameters.

Further examination of Table 3-5 reveals the trends of what stratification was present in the Middle Black Warrior and Tombigbee Rivers. Both rivers appear to be well mixed vertically in both December 1978 and April 1979 with a maximum surface to bottom temperature difference of  $3^{\circ}$ C at R-1 (Table D-2). It should be noted that the temperature difference is an increase from surface to bottom. The maximum DO decrease seen during these months is 1.3 mg/l (R-6,

ND = No data at station and date

<sup>\*</sup>From information provided by Mobile District, U.S. Army Corps of Engineers

December). This difference is obscured, however, by the DO super-saturation at the surface. By July 1979 these differences had increased such that several stations were displaying distinct, but still minor, vertical variation in DO and temperature.

Thermal stratification was apparent at several stations in July 1979. However, the average temperature decline was only  $0.5^{\circ}\text{C}$  with R-15 showing a full  $1^{\circ}$  lower at the bottom. At that same station, the D0 showed only 0.5 mg/l decline (8.1 mg/l to 7.6 mg/l, Table D-6). R-21 showed a  $1.5^{\circ}\text{C}$  decline in temperature with a 2.1 mg/l decline in D0. R-9, immediately upstream of Warrior Lock and Dam, had the highest D0 decline, 2.2 mg/l with a temperature drop of only  $0.5^{\circ}\text{C}$ . In October 1979 most stratification had disappeared. An exception was Demopolis Lake (R-22 and R-23) which showed some stratification during this month. Between the stations there was an average D0 decline of 1.0 mg/l and an average temperature drop of  $0.75^{\circ}\text{C}$ . As noted, these stratifications appeared for the only time in Demopolis Lake during October 1979. However, as with all other stations at all other sampling times, stratification never increased to the point of producing a distinct thermo- or chemocline.

The stations showing the highest stratification were R-9 behind Warrior Lock and Dam, the stations of the Lower Black Warrior River; R-20 and R-21 on the Tombigbee River and R-22 and R-23 in Demopolis Lake. Between these sections, the Lower Black Warrior River had more consistent DO and temperature declines than any other section (see Appendix D). Warrior Lake and the Tombigbee River showed the least amount of stratification.

The other in-situ parameters measured during these data collections (specific conductance, pH and ORP) displayed very little vertical variation. During July 1979, the period with maximum thermal and oxygen depletion over depth, specific conductance showed no change through the vertical profile. pH values consistently dropped off with increasing depth in all river sections, however, this decrease rarely exceeded ± 0.5 units. ORP, a measurement of the electrochemical potential, generally increased as DO levels decreased. However, at the maximum DO depletion, ORP did not vary. Indeed, ORP varied more horizontally than vertically. Thus, the other in-situ parameters showed less stratification than the major stratification indicators, DO and temperature.

# Extensive Mixing Studies

Extensive mixing studies were conducted during October 1978 and February and August 1979. The purpose of these studies was to determine the horizontal and vertical mixing of the river at all main stations. Thus, vertical profiles were taken at three points: near the right and left banks in the littoral zone and at mid-stream (over the deepest point). The results of these three data collections are presented in Appendix F.

Warrior Lake shows only minor vertical stratification during all three months. However, there are several instances of distinct horizontal stratification. In October 1978, surface water temperatures at station R-7 varied by 4°C from both littoral zones to mid-stream, with the littoral zones being colder (Table F-1). At R-5 during the

same month, DO showed an extreme horizontal variation. At the right bank the DO was supersaturated (11.0 mg/l). At mid-stream the DO fell off by 3.0 mg/l from the surface to the bottom. At the left bank the DO was only 5.6 mg/l throughout the entire water column. All other parameters were stable during this period at this station, except pH which was 2 units lower at the left bank than the right bank (see Table F-1). During February 1979, all parameters were relatively equal over both vertical and horizontal profiles (Table F-2). August 1979 measurements revealed only two major horizontal variations for parameters other than DO and temperature. Station R-6 recorded ORP values elevated by 25% (as compared to R-5) at all points (Table F-3). By station R-12 these elevated ORP had gradually returned to le:els near those of R-5. At R-9, surface temperatures were elevated by about 3-5°C in the littoral zones and DO levels were up to 1.0 mg/l higher in the river margins than that at mid-stream (Table F-3).

The Lower Black Warrior River showed different trends in vertical and horizontal stratification than Warrior Lake. One consistent difference between the two sections was the lowered DO levels to be found at the deepest part of mid-stream (see R-13 through R-16 on Tables F-1, F-2 and F-3). As noted in the previous section on stratification, this DO depletion with depth was greatest in the summer of 1979 (Table F-3) but never reached anaerobic levels at any station. The river was once again completely vertically mixed by the October 1979 sampling (Table D-7). Horizontal variation was less proncunced than in Warrior Lake. As with the upper section, littoral temperature in the lower Black Warrior River was occasionally different than the mid-stream temperatures. For example, for surface water temperatures at R-14 in October 1978, the littoral zones were 27°C and the midstream 25°C at the surface (see Table F-1). DO also showed similar horizontal stratification on the upper and lower sections, but no extreme transect variations were observed. At R-12 in August 1979, (Table F-3) the littoral zone surface DO was approximately 0.6°C higher than the midstream surface DO. This example is one of the larger variations (see Table F-1 through F-3). Thus, while the results of extensive mixing showed less horizontal variability in the Lower Black Warrior River as compared to the upper section, they did reveal the increased vertical stratification in this reach of the Black Warrior below Warrior Lock and Dam.

The Tombigbee River extensive mixing studies revealed both horizontal and vertical stratification. In October 1978, R-17 was well mixed in both dimensions (Table F-1). R-18, however, showed significatnt horizontal variation between the mid-stream and right bank. Midstream surface DO concentrations were 2.0 mg/l lower than the right bank surface levels. This lower DO was then observed at the left bank and mid-stream with surface DO concentrations at the right bank being elevated to near saturation. By R-20 the horizontal variation was gone but the DO levels were suppressed (5.2 to 5.6 mg/l). At R-21, the DO showed some recovery rising to 6.0 - 6.8 mg/l at the surface. As with the Black Warrior River, all in-situ parameters showed near complete mixing during the February 1979 (Table F-2) sampling. In August 1979 (Table F-3) most stations showed nearly equal emperatures, both horizontally and vertically, with variation in temperature generally ranging up to 2°C. The largest horizontal temperature variation was at R-20 which had a 30°C variation between the littoral zone (31.5°C at the right bank) and the midstream (28.5°C). In general, littoral zone temperatures were warmer and mid-stream deep water temperatures were colder within this range. R-20 also had the greatest variation in DO levels with a 2 mg/l horizontal variation (high littorals and low mid-stream) and a 2-3 mg/l vertical aifrerence. Other parameter exhibited only a minor degree of stratification.

Demopolis Lake showed very little vertical or horizontal stratification during either the October 1978 or February 1979 surveys (see Tables F-1 and F-2). In August 1979 at R-22 (Table F-3), there was a distinct surface DO drop at mid-stream and the left bank as compared to the surface DO at the right bank. At R-23 during the same month, all surface DO concentrations were noticeably lower than normal. Temperature variations at these stations in August were only  $1^{\rm O}{\rm C}$ , with the littoral zones being warmer. All other in-situ parameters were well-mixed during all samplings.

Extensive mixing studies conducted at main river stations revealed varying patterns of horizontal and vertical stratification. Water temperature evidenced significant stratification in the summer with the littoral zones and the surface water being the warmest. Winter water temperatures were essentially equal throughout the river. DO levels were seen to have significant horizontal stratifications with vertical stratifications being small and mostly related to stream depth. All other in-situ parameters were approximately equal during each sampling with only slight variations occurring between seasons (see Section 3.1.1.1).

# 3.1.1.3 Major Ions and Associated Parameters

The presentation of results for this Section and Sections 3.1.1.4 through 3.1.1.6 encompass data contained in Appendices A and B. These are raw data for chemical analyses and quality control support data, respectively. In contrast to the presentaion in Section 3.1.1.1, the following results concern only main river stations since tributary stations were monitored for in-situ parameters only.

Alkalinity. Alkalinity (4.5 S.U.) evidenced stable levels in all rivers and varied only slightly during the study. The highest mean alkalinity was 43 mg/l (all units as  $CaCO_3$ ) observed at R-20 and R-21 on the Tombigbee River (Table 3-8). The station having the lowest mean alkalinity was R-13, with 23 mg/l (Table 3-7). R-20 had the highest alkalinity recorded, 59 mg/l in early and late August 1978 (Table A-1 and A-2). R-13 had the lowest alkalinity, 23 mg/l, recorded in October 1978 (Table A-3).

The river sections also had stable alkalinities, with the grand means showing little variation from the station means. The Tombigbee River had the highest average alkalinity, 41 mg/l (Table 3-8). Demopolis Lake had the second highest average value, 28 mg/l (Table 3-9). This value was very close to that of Warrior Lake, which had an average alkalinity of 26 mg/l (Table 3-7). The Lower Black Warrior River average alkalinity dropped off slightly, being 24 mg/l (Table 3-6). These conditions indicate a very stable alkalinity for the rivers through the seasons and within the sections.

<u>Calcium</u>. The levels of calcium observed in the Middle Black Warrior and Tombigbee Rivers were highly variable but showed a consistent pattern.

PARAMETER	Tot e	Residue, Total Nonfilterable (mg/1)	CO <sub>2</sub> (calc.) (ng/1)

Station R-21 had the highest average calcium levels, 17.8 mg/l (Table 3-8). The lowest average calcium level was 6.3 mg/l observed at R-13 (Table 3-7). The single highest calcium concentration was 23.5 mg/l, recorded at R-20 in August 1979 (Table A-9); the single lowest was 3.4 mg/l at R-10 in February 1979 (Table A-5). Despite the magnitude of variation, one consistent trend was that all stations recorded higher calcium concentrations in the two August trips (Tables A-2 and A-9) than in February 1979 (Table A-5).

The Tombigbee River and the highest grand average for calcium, 16.5 mg/l (Table 3-8). Demopolis Lake with an average calcium concentration of 13.4 mg/l (Table 3-9) had the second highest mean. The Black Warrior River had 10.2 (Table 3-6) and 9.3 mg/l (Table 307) for the lake and the lower section, respectively. As noted above, the river sections showed high seasonal variability with summer maxima and early spring minima.

Magnesium. Concentrations of magnesium showed little variation, but a consistent seasonal trend. However, this trend was distinctly different than that noted for calcium (see above).

The station yielding the highest average magnesium concentration was R-2 (6.01 mg/l, Table 3-6). R-21 had the lowest average magnesium concentration, 1.99 mg/l (Table 3-7). The single highest magnesium level recorded was 8.3 mg/l at R-2 in August 1979 (Table A-9). The lowest value recorded for magnesium was 1.1 mg/l at R-17 in August 1978 (Table A-2). Considering all data, minimum concentrations for magnesium were recorded in August 1978 (Table A-2) and the maximum level in August 1979 (Table A-9).

Between the river sections, Narrior Lake had the highest average magnesium concentration, 5.48 mg/l (Table 3-6). The Lower Black Warrior River was slightly lower, 5.12 mg/l (Table 3-7). Demopolis Lake had a decrease of approximately 40% in magnesium concentrations with an average of 3.61 mg/l (Table 3-9). The Tombigbee River had the lowest average magnesium level, 2.12 mg/l (Table 3-8).

As stated above, magnesium displayed one pervasive trend. This was a rising magnesium level in Warrior Lake during the period of the study (see Tables A-2, A-5 and A-9). In contrast, stations R-10 through R-23 showed a trend similar to that noted for calcium: a peak in February 1979 (Table A-5), with a return to the August 1978 levels. During each sampling cited above the magnesium values rose steadily (progressing upstream).

Hardness (Calculated). Hardness had the least variation of any of the indicators of dissolved substances and generally displayed a trend similar to that of calcium. The station with the highest average hardness was R-3 (Table 3-6) with 70 mg/l (all units as CaCO<sub>3</sub>). The lowest average hardness was 46 mg/l observed at R-9 (Table 3-8). The maximum hardness was 87 mg/l recorded at R-3 in August 1978 (Table A-2). The minimum hardness was 36 mg/l which was recorded at R-10 in August 1978 (Table A-2). Generally, the lowest hardness occurred in February 1979 (Table A-5) and the highest occurred in August 1979 (Table A-9).

Although differences were slight, the Tombigbee River had the highest average hardness, 59 mg/l (Table 3-8) Demopolis Lake had an

average of 56 mg/l (Table 3-9). As with calcium, hardness in the Black Warrior was slightly higher in Warrior Lake (54 mg/l, Table 3-6) than the lower section (52 mg/l, Table 3-7). This trend is somewhat similar to that of calcium (see above) which is the major component of the calculated hardness.

Chlorides. The levels of chlorides observed during the study show both seasonal and sectional trends. The highest average chloride value was 10 mg/l, observed at two stations on the Tombigbee River, R-17 and R-20 (Table 3-8). The lowest average value was 5 mg/l observed at R-1, R-2, R-3 and R-5 (Table 3-6). The maximum chloride concentration recorded was 15 mg/l (R-18, August 1978, Table A-2). The minimum chloride concentration, 2 mg/l was recorded at all Tombigbee River Stations in February 1979 (Table A-5). Considering all chloride data, the lowest chloride concentrations were recorded in February 1979 (Table A-5). Overall maximum chloride concentrations were recorded in August 1978 (Table A-2).

The Tombigbee River had the highest grand average chloride concentration, 9 mg/l (Table 3-8). Warrior Lake and Lower Black Warrior River averaged 6 mg/l (Table 3-6) and 7 mg/l (Table 307), respectively. Demopolis Lake averaged between the two rivers, 8 mg/l (Table 3-9). These results indicate a seasonal fluctuation in chloride levels within the river sections which are moderately different from each other.

Potassium. Potassium, one of the major vascular plant nutrients, showed very little variation between both seasons and river sections. Tables 3-6 through 3-9 show the average sectional variation is  $\leq 0.2$  mg/l.

The station with the highest average potassium level was R-22 (2.53 mg/l, Table 3-9). The lowest average concentration was 1.98 mg/l potassium recorded at R-9 (Table 3-6). The maximum potassium concentration recorded was 3.52 mg/l (R-20, February 1979, Table A-5); the lowest was 1.24 mg/l at R-21 (August 1978, Table A-2). Generally, the lowest potassium concentrations were observed in August 1978 (Table A-2) and the highest in February 1979 (Table A-5).

Demopolis Lake had the highest grand average for potassium, 2.34 mg/l (Table 3-9). The Tombigbee River had 2.15 mg/l (Table 3-8) on the average. The Lower Black Warrior River (Table 3-7) had the second highest average 2.23 mg/l and Warrior Lake the lowest average, 2.14 mg/l (Table 3-6). The August 1978 and August 1979 trips (Tables A-2 and A-9, respectively) showed higher potassium values in the Black Warrior River basin than the Tombigbee River basin. The opposite situation occurred during the February collection (Table A-5). However, as previously stated, the differences are very small making potassium the most equally distributed element between the river basins.

Sodium. Sodium concentrations varied about 30% between both seasons and river sections. The highest average sodium concentration, 9.63 mg/l, was observed at R-16 (Table 3-7). The lowest average, 5.46 mg/l, occurred at R-18 (Table 3-8). The maximum sodium value recorded was 11.40 mg/l (R-6, Table A-2); the minimum, 0.68 mg/l, was recorded at R-9 (Table A-2). Both values were recorded during August 1978. Overall, the minimum sodium levels were observed in February 1979 (Table A-5) and the maximum in August 1978 (Table A-2).

Warrior Lake and the Lower Black Warrior River had the highest average sodium levels, 9.23 mg/l (Table 3-6\_ and 9.30 mg/l (Table 3-7), respectively. The Tombigbee River was approximately 40% lower, with a grand average of 5.98 mg/l (Table 3-8). Demopolis Lake had an average sodium concentration of 6.63 mg/l (Table 309). These results show only moderate variation between the river sections, with seasonal variations being more noticeable.

Dissolved Sulfates. Sulfates showed a greater seasonal variation, up to 200%, than any of the other ions investigated. The greatest average sulfate value observed was 47 mg/l (R-1 through R-4, Table 3-6). The lowest average sulfate value was 7 mg/l (R-20, Table 3-8). The maximum concentration of sulfate recorded was 65 mg/l at R-7 in October 1979 (Table A-10). The minimum sulfate level, 1 mg/l, was recorded at R-20 in August 1979 (Table A-9). Considering all stations, the lowest sulfate concentrations were observed in May 1979 (Table A-6) and the highest in October 1979 (Table A-10).

Sulfate values were the highest in Warrior Lake, averaging 44 mg/l for the study period (Table 3-6). The sulfate levels fell off slightly in the Lower Black Warrior River, with a grand average of 39 mg/l (Table 3-7). The Tombigbee River had the lowest average sulfate level, 8 mg/l (Table 3-8). Demopolis Lake had an intermediate sulfate average, 27 mg/l (Table 3-9). These results indicate a much greater variation in sulfate levels between river basins than between seasons.

1

<u>Sulfides</u>. Sulfide was an unusual parameter in that it was often below detectable limits (0.01 - 0.02 mg/l) but was occaionally quite high. The station with the highest average sulfide level was R-3 which had an average of 0.8 mg/l (Table 3-6). The lowest average sulfide was 0.1 mg/l recorded at stations in all river sections except the Tombigbee River (see Tables 3-6 through 3-9). As stated, the lowest sulfide concentration measured was non-detectable (<0.01 mg/l), which occurred at every station on several occasions (Appendix A). Overall, the lowest sulfide levels were in October 1978 (Table A-3), February 1979 (Table A-5) and May 1979 (Table A-6) when all stations had <0.01 mg/l sulfide. June 1979 (Table A-7) and October 1979 (Table A-10) had over 90% of the stations with <0.01 mg/l sulfide. However, June 1979 also recorded the highest sulfide concentration, 5.8 mg/l, at R-3 (Table A-7). (Note: The second highest sulfide level was also recorded in June 1979, 4.6 mg/l at R-13, this was 100% larger than the next highest value 2.1 mg/l recorded R-1 in August 1978, see Table A-2). August 1978 had the highest overall sulfide values (Table A-2).

The grand averages of the river sections showed very little variation between them. The Black Warrior River and the Tombigbee River had equal averages, 0.3 mg/l (Table 3-6, 3-7 and 3-8). Demopolis was slightly lower having an average of 0.2 mg/l (Table 3-9). Thus, sulfide concentrations were much more variable between seasons than between river sections.

Total Filterable Residue (Dissolved Solids). Levels of dissolved solids were relatively stable within each river section but had a moderate amount of masonal variation. The highest average amount of dissolved solids occurred at R-15 (180 mg/l, Table 3-7). R-17 had the lowest average dissolved solids level, 76 mg/l. The maximum dissolved solids concentration was 903 mg/l, recorded at R-15 in May 1979 (Table A-6); the minimum was 20 mg/l at R-10 in May 1979 (Table 5). The highest

overall dissolved solids levels were observed in October 1979 (Table A-10) and the lowest in May 1979 (Table A-6).

The Black Warrior River had the highest average dissolved solids levels of the river sections. The Lower Black Warrior River had the highest average, 122 mg/l (Table 3-7). Warrior Lake had a slightly lower value, 113 mg/l (Table 3-6). Demopolis Lake, with an average of 111 mg/l (Table 3-9), fell just between the Black Warrior and the Tombigbee River which had the lowest average, 91 mg/l (Table 3-8).

Total Non-filterable Residue (Suspended Solids). Suspended solids evidenced much greater variation than dissolved solids. R-19 had the highest average suspended solids load, 78 mg/l (Table 3-8). The lowest average suspended solids level, 8 mg/l, was observed at R-1 (Table 3-6). The single highest suspended solids concentration was 330 mg/l, recorded at R-20 in February 1979 (Table A-5). The minimum suspended solids concentration was <1 mg/l, recorded at R-13 in October 1978 (Table A-3). The highest monthly suspended solids loads were observed in February 1979 (Table A-5); the lowest were in October 1978 (Table A-3).

The Tombigbee River had the highest grand average for suspended solids, 61 mg/l (Table 3-8). The Lower Black Warrior and Demopolis Lake had equal levels, 28 mg/l (Table 3-7 and 3-9, respectively). Warrior Lake carried the lowest average suspended solids loading, 16 mg/l (Table 3-6). These results show extreme variations in suspended solids loading, both between seasons (the greatest variation) and between river sections.

Free Carbon Dioxide (Calculated). Average values for free carbon dioxide ( $CO_2$ ), show little variation between river sections, but rather large variations between seasons. The station with the highest average  $CO_2$ , 7.5 mg/l, was R-1 (Table 3-6). R-19 had the lowest average  $CO_2$ , 2.4 mg/l (Table 3-7). The highest recorded  $CO_2$  level was 34 mg/l at R-5 in July 1978 (Table A-1). The lowest  $CO_2$  was <0.1 mg/l, recorded at R-5 in October 1978 (Table A-3). October 1979 also had the overall lowest  $CO_2$  values. The highest  $CO_2$  values for the study were observed in February 1979 (Table A-5).

Warrior Lake had the highest grand average for  $\rm CO_2$ , 4.6 mg/l (Table 3-6). The Lower Black Warrior River had slightly lower concentration of  $\rm CO_2$ , with a study period average of 4.2 mg/l (Table 3-7). Demopolis had an average of 3.6 mg/l (Table 3-8) and the Tombigbee was consistently the lowest, with an average of 3.2 mg/l (Table 3-9). These variations between sections are minor, compared to the larger variations which were observed between seasons.

#### 3.1.1.4 Nutrients

Nutrients, as defined in this section, are confined to various components and compounds considered in the nitrogen series, dissolved orthophosphate and total phosphorus. Summarized data for nutrient concentrations are found in Tables 3-10 through 3-13 in this section. Raw data from the monthly samplings are found in Appendix A.

Ammonia. Concentrations of ammonia had considerable seasonal variation with only minor variation within and between sections. R-15

Means and Ranges of Nutrients at Main River Stations, Middle Black Warrior River, Stations R-1 thru R-9 (Warrior Lake), July 1978 through October 1979 TABLE 3-10.

FARAMETER	Ammonia-N (ng/1)	Nitrate- Nitrite-N (mq/l)	Total Kjeldahl-N (my/l)	Total Inorgan- ic-N (calc.) (mq/l)	lotal Organic N (calc.) (mg/l)	Total N (calc.) (mq/l)	Dissolved Orthophosphate (mq/1)	Total Phosphorus (mg/1)

had the highest average ammonia level,  $0.36 \, \text{mg/l}$  (Table 3-11). The lowest average ammonia level,  $0.09 \, \text{mg/l}$ , occurred at R-6 (Table 3-10) and R-20 (Table 3-12). The maximum ammonia concentration observed during the study was  $0.36 \, \text{mg/l}$  at R-13 in February 1979 (Table A-5). The minimum ammonia concentration was non-detectable (<0.01 or <0.03  $\, \text{mg/l}$  depending on month) which was recorded at several Lower Black Warrior River and Tombigbee River stations during July and August 1978 (Tables A-1 and A-2). Considering all stations, the lowest ammonia levels were observed in August 1978 (Table A-2) and the highest in July 1979 (Table A-8).

On the average, the river sections were close in their ammonia concentrations. The Lower Black Warrior River had the highest grand average, 0.13 mg/l (Table 3-11). Warrior Lake, the Tombigbee River and Demopolis Lake averaged 0.11 mg/l (Tables 3-10, 3-12 and 3-13, respectively). These results indicate a seasonal variation for ammonia approaching 3 orders of magnitude with only moderate differences existing in yearly averages between the river sections.

Nitrate-Nitrite. Levels of nitrate-nitrite-nitrogen were as variable by season as ammonia and they had a greater variation by river section. R-4 had the highest average concentration of nitrate-nitrite, 0.67 mg/l (Table 3-10). The lowest average nitrate-nitrite level, 0.18 mg/l, occurred at R-18 and R-19 (Table 3-12). The maximum nitrate-nitrite concentration recorded during the study was 1.20 mg/l at R-13 during June 1979 (Table A-7). The minimum nitrate-nitrite level observed was <0.01 mg/l (R-19 and R-20, Table 3-12). June 1979 (Table A-7), showed the highest monthly nitrate-nitrite values while the lowest occurred in October 1979 (Table A-3).

Warrior Lake had the highest grand average nitrate-nitrite value, 0.58 mg/l (Table 3-10) and the Lower Black Warrior had a slightly smaller average, 0.51 mg/l (Table 3-11). The Tombigbee River had the lowest study period average, 0.21 mg/l (Table 3-12) with Demopolis Lake having an intermediate average, 0.42 mg/l (Table 3-13). Thus, nitrate-nitrite had both large seasonal and river section variations.

Total Kjeldahl Nitrogen. Trends of total Kjeldahl nitrogen (TKN) were different than those exhibited by the othe nitrogenous compounds. The station with the highest average TKN was R-19 with 0.87 mg/l (Table 3-12). R-10 had the lowest average TKN, 0.37 mg/l (Table 3-11). The maximum TKN concentration was 1.80 mg/l, recorded R-20 in February 1979 (Table A-5); the minimum was 0.10 mg/l recorded at several stations in the Black Warrior River during several months (Appendix A). The month with the lowest TKN levels was August 1978 (Table A-2). The highest overall TKN concentrations were observed in May 1979 (Table A-6).

TKN levels were the highest in the Tombigbee River, which had a study period average of 0.74 mg/l (Table 3-12). Demopolis Lake was slightly lower with an average of 0.63 mg/l TKN. Warrior Lake had an average of almost 50% less TKN than the Tombigbee River (0.44 mg/l, Table 3-10), with the Lower Black Warrior River being slightly higher (0.53 mg/l, Table 3-11). These results indicate high levels of TKN, with the sectional distribution being quite different than that of ammonia or nitrate-nitrite-nitrogen.

Total Inorganic Nitrogen (Calculated). Total inorganic nitrogen (TIN) represents the sum of the ammonia nitrogen and nitrate-nitrite nitrogen which is the total available nitrogen for plant growth (U.S. EPA, 1978). Due to the method of calculation, trends for TIN generally followed the trends of the major component, nitrate-nitrite.

The highest average TIN level observed was 0.75 mg/l at R-1 and R-2 (Table 3-10); the lowest was 0.25 mg/l at R-19 and R-20 (Table 3-12). The maximum value calculated for TIN was 1.42 mg/l at R-23 in June 1979 (Table A-7). The minimum TIN during the study period (dismissing the summation of nondetectable components) was 0.01 mg/l at R-20 in August 1978 (Table A-2). TIN levels were generally the lowest during October 1978 (Table A-3) and the highest during June, 1979 (Table A-7).

The river section trends for average TIN values are parallel to those trends for nitrate-nitrite. Warrior Lake had the highest average, 0.67 mg/l (Table 3-10) with the Lower Black Warrior River averaging slightly less, 0.64 mg/l (Table 3-11). The Tombigbee River had a much lower average TIN (0.27 mg/l, Table 3-12) and Demopolis Lake showed an average TIN level between the two rivers, 0.53 mg/l (Table 3-13).

Total Organic Nitrogen (Calculated). Total organic nitrogen (TON) represents the concentration of TKN minus the concentration of ammonia nitrogen. TON, then, is that part of the nitrogen load which is oxidizable and would be a nitrogenous oxygen demand.

The highest average TON level observed during the study was 0.80 mg/l at R-19 (Table 3-12). The lowest average TON was observed at R-8 (0.22 mg/l, Table 3-10). R-20 had the single highest TON level, 1.80 mg/l, recorded in February 1979 (Table A-5). The minimum TON level observed during the study, which was <0.10 mg/l, occurred at several Black Warrior River and Demopolis Lake stations during August 1978 (Table A-2), October 1978 (Table A-3), February 1979 (Table A-5) and June 1979 (Table A-7). Considering all stations during a month, October 1978 (Table A-3) recorded the lowest TON values while May 1979 had the highest values for the Black Warrior River (Table A-6) and February 1979 (Table A-5) had the highest TON levels on the Tombigbee River.

Trends for river sections distirubiton of TON were generally similar to trends set by TKN levels. The Tombigbee River had the highest average TON level, 0.66 mg/l (Table 3-12). Warrior Lake had the lowest average TON level, 0.32 mg/l (Table 3-10) with the Lower Black Warrior River having a 30% higher average TON loading, 0.42 mg/l (Table 3-11). Demopolis Lake had an average TON between the values for the two rivers, 0.47 mg/l (Table R-13). These data indicate a distribution of oxidizable nitrogen which varies extensively by season and river section and closely follows the average concentration of TKN.

Total Nitrogen (Calculated). The levels of total nitrogen (TN) were calculated by summing the TIN and TON calculated values at each station. The highest average TN level observed during the study was 1.2 mg/l at R-16 (Table 3-11). The lowest average TN level observed was 0.8 mg/l which occurred most frequently in the Tombigbee River (Table 3-12). The maximum TN concentration observed during the study, 2.4 mg/l, was recorded at R-16 in May 1979 (Table A-6); the minimum,

0.2 mg/l occurred at several Tombigbee River stations in October 1978
(Table A-3).

Warrior Lake, the Lower Black Warrior River and Demopolis Lake had equal average TN values, 1.0 mg/l (Tables 3-10, 3-11 and 3-13). The Tombigbee River averaged 0.9 mg/l TN (Table 3-12). These results show that, despite seasonal and spatial variations, the two rivers were receiving approximately equal total nitrogen loadings, while the forms varied extensively.

Dissolved Orthophosphate. Concentrations of dissolved orthophosphates (ortho-P) exhibited extreme variations between stations, seasons and river sections. R-3, on Lake Warrior, had the highest average ortho-P level, 0.16 mg/l (Table 3-10). The lowest average ortho-P concentration recorded during the study, 0.011 mg/l, occurred at R-8 (Table 3-10) and R-13 (Table 3-11). The maximum ortho-P concentration observed was 0.272 mg/l (R-18, May 1979, Table A-6); the minimum, <0.001 mg/l, was recorded at stations in all river sections (see Table 3-10 through 3-13), primarily during July and August 1978 (Tables A-1 and A-2, respectively). May 1979 had the overall highest ortho-P values (Table A-6) while July 1978 (Table A-1) had the overall lowest ortho-P concentrations.

The Tombigbee River showed the highest study period average, 0.046 mg/l (Table 3-12). The Upper Black Warrior River had higher average levels of ortho-P than did the lower Black Warrior River, with 0.035 and 0.015 being the respective average levels (Tables 3-10 and 3-11, respectively). Demopolis Lake had an average ortho-P concentration of 0.037 mg/l (Table 3-13), a value falling between the levels of the two rivers. Thus, ortho-P had widely varying concentrations between seasons and river basins.

Total Phosphorus. Total phosphorus concentrations were much higher than ortho-P levels, but showed similar variations. The highest average phosphorus concentration was 0.250 mg/l, observed at R-17 and R-18 (Table 3-12). The lowest average phosphorus level was 0.035 mg/l (R-3, Table 3-10). The maximum concentration of phosphorus observed during the study was 0.650 mg/l recorded at R-13 in June 1979 (Table A-7; note that this is an unusually high value for that month). The minimum observed level for phosphorus was 0.010 mg/l, recorded in the Black Warrior River and Lake Demopolis on several occasions (see Appendix A). Overall the lowest phosphorus levels occurred in July 1979 (Table A-1) and the highest levels were in February 1979 (Table A-5).

The Tombigbee River had the highest average phosphorus levels, 0.180 mg/l (Table 3-12). Warrior Lake was lower in total phosphorus than the Lower Black Warrior River with the average levels being 0.055 mg/l (Table 3-10) and 0.092 mg/l (Table 3-11), respectively. Demopolis Lake averaged somewhat higher than the Black Warrior River, 0.110 mg/l (Table 3-13). The patterns in the distribution of phosphorus between the river basins is similar to that of ortho-P with the average values being up to 100% greater for total phosphorus.

# 3.1.1.5 Heavy Metals

Summarized in this section are the results of heavy metal analyses performed on water samples on monthly or quarterly bases. Table 3-14

through 3-17 present the summarized data. Raw data for the individual samplings are found in Appendix A.

Dissolved Iron. Trends for concentrations of dissolved iron showed extreme variations between river sections and seasons. The highest average concentration for dissolved iron was 352 µg/l at R-18 (Table 3-16). R-2 had the lowest average dissolved iron, 58 µg/l (Table 3-14). The single highest dissolved iron concentration was 882 µg/l, recorded at R-18 in February 1979 (Table A-5). Because of the variable detection limit for dissolved iron, the lowest concentration is a "less than" value which was recorded for several stations in both sections of the Black Warrior River and in the Tombigbee during several months (see Tables 3-14, 3-15, 3-17 and Appendix A). Generally, the highest values were recorded in February, 1979 (Table A-5) and the lowest were during August 1979 (Table A-9) when most stations showed non-detectable dissolved iron concentrations.

The Tombigbee River had the highest average levels of dissolved iron, 260  $\mu$ g/l (Table 3-16), Demopolis Lake had the second highest level, an average of 115  $\mu$ g/l dissolved iron (Table 3-17). Warrior Lake had the lowest average value, 78  $\mu$ g/l (Table 3-14) with the Lower Black Warrior River averaging slightly higher, 96  $\mu$ g/l (Table 3-15). Thus, the results for dissolved iron showed both extreme seasonal variation, up to 300%, and a river basin variation of approximately the same magnitude.

Total Iron. The concentrations of total iron showed the same general trend of seasonal and spatial variation as dissolved iron. Station R-19 nad the highest average concentration of total iron, 3.77 mg/l (Table 3-16). The lowest average concentration was 0.45 mg/l, recorded at R-1 (Table 3-14). The single highest total iron level was 18.40 mg/l, observed at R-19 in February 1979 (Table A-5); the lowest was at R-1 (0.18 mg/l, August 1978, Table A-2). Generally, the highest total iron levels were observed in February 1979 (Table A-5). While August 1979 (Table A-9) may show the lowest overall values for total iron, it should be noted that this "base level" appeared (with about 25% variation) on several occasions.

The Tombigbee River, with a grand average of 3.37 mg/l (Table 3-16), had the greatest constant concentrations of total iron. Warrior Lake had the lowest average levels of total iron, 0.87 mg/l (Table 3-14). The Lower Black Warrior River had a slight increase in average total iron concentration with 1.39 mg/l being the average for the study period (Table 3-15). Demopolis Lake had a value intermediate of the two rivers, 1.80 mg/l (Table 3-17). The results for total iron indicate that iron distributions in study area (both total and dissolved iron) have drastic seasonal fluctuations, with the Tombigbee River carrying a consistently higher iron loading than the Black Warrior River.

Dissolved Manganese. Concentrations of dissolved manganese showed markedly different trends from the trends of iron in the study area. R-1 had the highest average levels of dissolved manganese, 128 µg/l, (Table 3-14). The lowest average level of dissolved manganese, 22 µg/l, occurred at R-21 (Table 3-16). The maximum single concentration of dissolved manganese, 419 mg/l, occurred at R-10 in February 1979 (Table A-5). The minimum value, non-detectable (with a variable lower limit),

was recorded at every station at least twice, most notably in June and July 1979 (Tables A-7 and A-8, respectively) when all stations showed <50  $\mu$ g/l. Overall, the highest values were recorded in February 1979 (Table A-5) and, as noted, the lowest in the summer of 1979.

Warrior Lake had the highest average dissolved manganese level 103  $\mu$ g/l (Table 3-14). The Lower Black Warrior River had an average slightly less than the upper section, 84  $\mu$ g/l (Table 3-15). The Tombigbee River had the minimum average, 26  $\mu$ g/l (Table 3-16). Demopolis Lake, with a study period average of 42  $\mu$ g/l dissolved manganese, fell between the two river levels. Thus, the Black Warrior River carried higher dissolved manganese loadings which showed extreme seasonal variations, and the Tombigbee River was much lower, both in loading and in variation.

Total Manganese. Total manganese concentrations were much more similar between the river sections than was dissolved manganese. The highest average total manganese level was 209  $\mu g/l$  at R-5 (Table 3-14). The lowest average total manganese was 84  $\mu g/l$  at R-21 (Table 3-16). The maximum total manganese level observed during the study was 720  $\mu g/l$  at R-14 in February 1979 (Table A-5). The lowest total manganese concentrations observed was <10  $\mu g/l$  at R-19 in August 1978 (Table A-2). Several other instances of "less than" levels were observed, but conditions during this month allowed for detection of the minimum concentrations. Overall, the lowest total manganese concentrations apparently in July 1979 and August 1979 (Tables A-8 and A-9, respectively). The maximum levels of total manganese occurred in the whole study area during February 1979 (Table A-5).

As with dissolved manganese, Warrior Lake, with 166  $\mu$ g/l (Table 3-14), had the highest average total manganese levels. The Lower Black Warrior River showed a slightly lower average 141  $\mu$ g/l (Table 3-15). The Tombigbee River had very much lower average total manganese levels than the Black Warrior River with the grand average being 108  $\mu$ g/l (Table 3-16). Demopolis Lake had the same average, 108  $\mu$ g/l (Table 3-17). Thus, total manganese had much closer average values between the river sections, while seasonal fluctuations were just as great as for dissolved manganese.

Total Zinc. Total zinc levels in the Middle Black Warrior-Tombigbee Rivers showed little variations between the river basins. However, seasonal fluctuations were as great as 1000%. The highest average level of zinc was 178 µg/l, recorded at R-12 (Table 3-15). R-19 had the lowest average zinc concentration, 40 µg/l (Table 3-16). The maximum zinc level, 896 µg/l, was recorded at R-4 in October 1978 (Table A-3). The minimum value observed during the study, <10 µg/l was recorded at every station at least once. The overall lowest zinc levels were observed during June 1979 (Table A-7) and August 1979 (Table A-9) when approximately 75% of the stations had <10 µg/l zinc. October 1978 had the overall highest concentrations of zinc (Table A-5).

The range between river sections for average zinc concentrations was very small,  $13~\mu g/l$ . Warrior Lake averaged 83  $\mu g/l$  (Table 3-14), the Lower Black Warrior River averaged slightly greater, 89  $\mu g/l$  zinc, which was the highest average for a river section (Table 3-15). The Tombigbee River had the lowest average zinc concentration, 76  $\mu g/l$ 

(Table 3-16). Demopolis Lake had an average of 84  $\mu$ g/l zinc for the study period. Zinc concentrations were much more consistent, on the average, between the river sections than any other heavy metal studied. However, zinc did display extreme seasonal variations.

Table 3-18 presents a summary of these analyses as performed on the samples from the Middle Black Warrior and Tombigbee Rivers. Precision data showed very good reproductibility for titration analyses (e.g., chlorides with an average range of 0.35 mg/l), automated analyses with the Technicon Autoanalyzer (e.g. TKN with a range and standard deviation of 0.2 mg/l) and manual analyses such a turbidity. The atomic absorption (AA) analyses (e.g. total and dissolved iron, zinc) showed much higher ranges, however, average accuracies were very good for these same parameters. This is not an unusual occurrence for AA analyses at the low-levels which occurred during this study. Accuracy data also showed that the automated analyses (i.e. nitrogen series on the Technicon) and instrument analyses such as carbon analyses, had a very good record of performance for the study.

The QC analyses performed during this study, gave the data an overall more valid stance since it allowed for rapid assessment of the validity of the data being produced. Although not shown on Table 3-18, several series of analyses were rejected as being "out of control" and were repeated. Most notably, this happened on a few occasions with total non-filterable residue and dissolved organic carbon. In July 1979 TKN analyses were repeated four times trying to bring them "in-control" according to the Shewhart charts. Finally, before reproducible results were obtained, samples had exceeded their holding time and were not reported. Thus, the QC procedures utilized for this project allowed for reporting only data which met statistical validity for the analyzing laboratory.

## 3.1.2 Sediment Analyses

#### 3.1.2.1 Grain Size Analysis

Two sediment grain size analyses were performed during this study as shown in Table 1-6. The results of these analyses are presented in tabular form in Appendix H and are summarized in Table 3-19. Appendix I contains a graphic presentation of the grain size distribution at each station (Table 3-18).

The results of the two annual analyses indicate that some sections experienced a shift in sediment grain size distribution (see 3.1.1.1 for a description of the river sections within the study area). Warrior Lake stations had a shift in average composition which represented a redistribution of sands and the addition of some clay materials. However, these changes were not severe enough to change the general sediment classification for the section, although several stations did have a reduced gravel content (see Tables H-1 and H-2). A similar redistribution of the sand and fine content shifted the general classification of the Lower Black Warrior River in 1979 from loamy sand to sandy loam (Table 3-19). Thus, the Black Warrior River experienced only minor changes in the grain size distribution. In contrast, the Tombigbee River and Demopolis Lake in particular, experienced much larger shifts in sediment composition.

MICROCOPY RESOLUTION TEST CHART NATIONAL BUREAU OF STANDARDS-1963-A

The Tombigbee River in 1978 had the general classification of sandy loam (Table 3-19). By the 1979 sampling this had changed to gravelly sandy clay loam. This change was chiefly caused by the increased measurement of gravels at R-17 (Table H-2) and an increase in the total clay content at R-19, R-20 and R-21 (Table H-2). No clays were present in the 1978 sample (Table H-1). Demopolis Lake also experienced this tremendous increase in clay materials, rising from an average of 14% clay in 1978 (Table H-1) to 27% in 1979 (Table H-2). The increase at R-22 was the largest, going from no clays in 1978 to 36% clay in 1978 while R-23 evidenced a small decline (Table H-1 and H-2). The Tombigbee River had a larger sediment deposit in the lower reaches, including Demopolis Lake, in 1979 than in 1978. This was accompanied by a percentage increase in gravel for stations on the Tombigbee River. In comparison, the Black Warrior River sediment composition remained relatively unchanged over the study period.

# 3.1.2.2 Physical-Chemical Analyses

At the time of the yearly sediment samplings (Table 1-5), several physical-chemical tests were performed (Table 1-6). These analyses included volatile solids, nutrients, heavy metals and pesticides. Tabular presentations of the results are found in Appendix J.

## Miscellaneous Parameters

Volatile Solids. Levels of volatile solids in sediments remained relatively unchanged between 1978 and 1979 at most Black Warrior River stations, while the Tombigbee River showed a general decrease in volatile solids levels and Demopolis Lake remained essentially the same. The highest level for volatile solids in Warrior Lake was 30,000 mg/kg in 1978 (R-8, Table J-1) and 34,000 mg/kg in 1979 (R-1, Table J-3). The Lower Black Warrior River had approximately one-half the volatile solids level as the upper sections, but showed a high of 31,000 mg/kg (R-16, Table J-1) and a 1979 high of 22,000 mg/kg (R-24, Table J-3). These high levels are typical of the river section, and the general observation of the upper river having half the volatile solids levels of the lower river holds true (see Tables J-1 and J-3).

The Tombigbee River had the overall highest volatile solids levels in 1978, ranging from 10,000 mg/kg at R-17 to 63,200 at R-20 with a steady increase between those stations (Table J-1). This trend was not present in 1979, however, as volatile solids levels fluctuated between 9,800 mg/kg and 41,000 mg/kg (Table J-3). Demopolis Lake was relatively stable during the one year study period, maintaining a similar average value (approximately 40,000 mg/kg, although the stations in which showed the maximum levels reversed (Table J-1 and J-3). Overall, the levels of sediment-associated volatile solids fluctuated with river section.

Oil and Grease. The sediment levels of oil and grease did not exhibit any trends or patterns according to river sections or seasonal change in levels. One consistent observation is that the highest sediment-associated levels of oil and grease were recorded at R-1 during both years (216 mg/kg in 1978, Table J-1; and 135 mg/kg in

1979, Table 1-3). During both years the Tombigbee River showed values about 30% lower on the average than the Black Warrior River (see Table J-1 and J-3). R-21, which was not sampled in 1978, was an exception in 1979 when it rose more than 50% over the neares. Tombigbee River station (R-2C, 47 mg/kg) to 106 mg/kg (Table J-3). Demopolis Lake oil and grease values rose sharply in August 1979 over the 1978 values, which had a 1978 value of 13 mg/kg, was 52 mg/kg in 1979 (Table J-1 and J-3, respectively). The <1 mg/kg oil and grease level at R-23 in 1978 (Table J-1) had been replaced by 51 mg/kg in 1979 (Table J-3). Therefore, although the general trend at about 60% of the stations in the study area was increased levels of oil and grease in 1979, remaining stations showed decreases or stable levels.

Total Organic Carbon. As with volatile solids, total organic carbon (TOC) showed varying patterns over the study period, with a general trend towards decreased levels in 1979. The highest value recorded in 1978 was 38.4 g/kg at R-1 (Table J-1). The high in 1979, 27.3 g/kg was also recorded at R-1 (Table J-3). The remaining stations in Warrior Lake were much lower than R-1 during both years, although 1978 values were consistently higher (Tables J-1 and J-3). The Lower Black Warrior River had approximately equal TOC levels as the majority of stations in Warrior Lake during each sampling with approximate averages being 8 g/kg in 1978 and 3.5 g/kg in 1979, again showing a decrease in 1979.

The Tombigbee River varied slightly from this trend by having overall lower values in 1978 than in 1979. The highest Tombigbee River values were 12.5 g/kg in 1978 (Table J-1) at R-19 and 11.0 g/kg at R-20 in 1979 (Table J-3). However, the other Tombigbee River stations were higher in 1979 by 0.7 to 7 times (Tables J-1 and J-3). Demopolis Lake had values about 50% lower during 1979 than during 1978 (Table J-1 and J-3).

#### Nutrients

Total Kjeldahl Nitrogen. Levels of total Kjeldahl nitrogen (TKN) in sediments were relatively evenly distributed over the entire study area. An extreme change in magnitude was observed over the study period with levels increasing up to 500% in 1979 over the 1978 levels. The average level in Warrior Lake stations in 1978 was approximately 100 mg/kg (Table J-1) while it was near 300 mg/kg in 1979 (Table J-3). The Lower Black Warrior River TKN levels dropped off about 50% from those in Warrior Lake during each year. The Tombigbee River showed a downstream increase in 1978 (Table J-1). In 1979 this trend occurred again, but was not as consistent as in 1978. consistent observation was that R-20 had the highest TKN during each sampling: 295 mg/kg in 1978 (Table J-1) and 686 mg/kg in 1979 (Table J-3). Demopolis Lake had relatively low concentrations in 1978 (41 mg/kg at R-22, 39 mg/kg at R-23, Table J-1), comparable to the Lower Black Warrior River levels. In 1979, these levels had dramatically increased to 662 mg/kg at R-22 and 413 mg/kg at R-23 (Table J-3). Thus, while distribution patterns were fairly stable over the study period, the levels increased dramatically in 1979, especially the accumulation noted in Demopolis Lake.

Total Phosphorus. For Warrior Lake, levels of phosphorus were noticeably reduced during 1979 compared to 1978 levels, being about 20% lower overall. There was no large variation between the river sections during any one year except that the Tombigbee River showed higher values than other sections in 1979. The Black Warrior River showed relatively stable levels of sediment-associated total phosphorus during each year. The average value for the river was approximately 250 mg/kg in 1978 and 200 mg/kg in 1979. The Tombigbee River was not as stable. Total phosphorus levels in the upper reaches of the river in the study area were relatively low during each sampling (comparable to Black Warrior River levels) but at R-19 or R-20 (depending on the year) the values increased tremendously. For example, in 1978 R-18 was 273 mg/kg and R-19 was 504 mg/kg (Table J-1). In 1979, R-19 was 291 mg/kg and R-20 was 467 mg/kg (Table J-3). These elevated levels were present downstream in the Tombigbee River and Demopolis Lake. The highest value in the 1978 sampling was 673 mg/kg at R-23; in 1979 it was 502 mg/kg at R-22 (Tables J-1 and J-3 respectively). Thus, the only consistent observation during the study was the high level of sediment-associated phosphorus occurring in Demopolis Lake. All other stations and river sections showed fluctuations in sediment-associated total phosphorus, with the general decrease in concentration in 1979.

## Heavy Metals

The Color Co

Copper. Sediment-associated copper levels showed definite changes both in concentration levels between samplings and concentration levels in the river sections. The Black Warrior River had relatively low levels of copper in the sediment during the 1978 sampling. The highest values in Warrior Lake during this trip occurred at stations R-5, R-7 R-8 had the highest value for the section at 4.64 mg/kg. Immediately downstream from Warrior Lock and Dam, in the Lower Black Warrior River, values in 1978 were below 1 mg/kg and rose steadily to the highest value for that section at R-16, 6.22 mg/kg. Copper levels were lower on the Tombigbee River than in the Black Warrior River, being very low in the upper reaches and increasing to 3.4 mg/kg by Demopolis Lake. These same trends of high and low values occurred during 1979, except that concentrations were higher. For example, the high at R-8 in 1979 was 8.3 mg/kg (Table J-3) and 10 mg/kg was the highest single level of sediment-associated copper observed (R-6, Table J-3). The trend of lower values below Warrior Lock and Dam and in the Tombigbee River also occurred in 1979. Demopolis Lake showed the same high levels, compared to the other sections, in 1979 with 9.4 mg/kg at R-22 being the highest for the section.

Thus, concentrations of sediment-associated copper varied widely between river sections and years. Overall, concentrations in 1979 were much higher, up to 500%, than the 1978 samples.

Iron. Sediment-associated iron occurs primarily as a mineral constituent in the sediment materials. Warrior Lake had relatively high iron values during both samplings, with the 1979 values being about 50% greater than the 1978 values (Tables J-1 and J-3). The maximum iron level in the Warrior Lake section was observed at R-8 in both years with mg/kg in 1978 (Table J-1) and 20,000 mg/kg in 1979

(Table J-3). Below Warrior Lock and Dam (R-10 and R-12) concentrations were generally lower than those above the dam, but by R-16 had returned to levels comparable with the upstream stations. Sediment associated iron in the Tombigbee River was approximately at the same concentrations as Warrior Lake (see Tables J-1 and J-3). The 1979 values for iron in the lower reaches of the Tombigbee River and in Demopolis Lake were much higher than the 1978 levels in the same river sections. This was especially the case at R-22 which rose from 1100 mg/kg in 1978 (Table J-1) to 21,000 mg/kg in 1979 (Table J-3).

These results indicate a relatively stable level of sediment-associated iron in the Middle Black Warrior and Tombigbee Rivers during a single sampling. The only marked change between the 1978 and 1979 samplings was the rise in the lower reaches of the Tombigbee River and Demopolis Lake, with a general marked rise overall noted for 1979.

opposit - receptorates - marinalistics - and opposit - appoint the

Sediment-associated lead appeared to have stable distributions during the study period. While some stations showed definite increases in lead levels during the 1979 samplings over 1978 levels, overall the levels remained low and relatively unvarying. Warrior Lake had consistent lead levels both years with the section average being approximately 10 mg/kg each year. The Lower Black Warrior River evidenced a distinct drop in lead levels below Warrior Lock Dam during both years (see R-10 and R-12 values, Tables J-1 and J-3). R-14 and R-16 had especially high values, 13.5 mg/kg and 15.8 mg/kg, respectively, in the 1978 sampling (Table J-1) which were not present in the 1979 results (Table J-3). The Tombigbee River sediment-associated lead levels were generally lower than the Black Warrior River lead levels in 1978 (Table J-1). In 1979 the Tombigbee River showed some marked increases bringing Tombigbee River lead levels close to those in the Black Warrior River sediments. R-17 had 20 mg/kg lead (versus 3.0 mg/kg lead in 1978). R-20 and R-21 in the lower reaches of the Tombigbee River also had elevated lead levels, 10 mg/kg and 12 mg/kg, respectively (Table J-3). Demopolis Lake did not show this increase in 1979. The average for lead at R-22 and R-23 was essentially the same during both years, 12 mg/kg. Thus, lead is a relatively stable sediment constituent with a sporadic variation between sampling years.

Trends for manganese varied between the river sections, but in 1979 did show a general decreasing trend at most stations. Except for R-1 and R-2, Warrior Lake had relatively high values in 1978, averaging about 600 mg/kg manganese. This section had approximately the same average in 1979, although the concentrations were more unevenly distributed. For example, 1978 manganese values at R-3 and R-4 (637 mg/kg and 570 mg/kg, respectively, Table J-1) had shifted to lower values in 1979 (Table J-3) with a concomitant rise in manganese levels (to a river section maximum of 760 mg/kg at R-6; Table J-3) at R-5 and R-6. The Lower Black Warrior River exhibited similar trends between samplings. The lower stations in this section (R-14 through R-16) decreased in manganese while the stations immediately below Warrior Lock and Dam gained manganese (e.g. R-12 rose from 139 mg/kg in 1978 to 270 mg/kg in 1979, see Table J-1 and J-3). The maximum change in this section occurred at R-14 which decreased from the overall highest value for 1978, 862 mg/kg (Table J-1), to 310 mg/kg in 1979 (Table J-3). The Tombigbee River showed a tremendous accumulation of manganese at R-17, from 76 mg/kg in 1978 (Table J-1) to 320 mg/kg in 1979 (Table J-3). Overall, the Tombigbee River in 1970 had a slight decrease in sediment manganese

levels from the 1978 levels. Demopolis Lake showed an overall accumulation of manganese in 1979 rising from an average (for R-22 and R-23) of 328 mg/kg in 1978 (Table J-1) to 590 mg/kg in 1979 (Table J-3). Thus, while the Black Warrior River and the Tombigbee River showed, with the exception noted above, an overall decrease in sediment-associated manganese levels from 1978 to 1979, Demopolis Lake had a nearly 100% increase in manganese levels.

Sediment-associated mercury levels showed marked decrease between 1978 and 1979 samples. The lowest value in 1978 was 0.01 mg/kg (R-10, Table J-1) and the highest was 0.26 mg/kg (R-12, Table (R-1Table J-3). In comparison, the lowest value recorded in 1979 was 0.02 mg/kg (at several stations including R-12; see Table J-1), while the highest was only 0.11 mg/kg (R-18, Table J-3). Warrior Lake had relatively high values in 1978 at R-2 through R-6 (Table J-1), but in 1979 all Warrior Lake stations had decreased to 0.1 mg/kg or less, except R-8. R-8 showed a 150% increase in 1979, changing from 0.04 mg/kg in 1978 (Table J-1) to 0.10 mg/kg in 1979 (Table J-3). Most stations in the Lower Black Warrior River showed a decrease during the study period, as did all Tombigbee River (Table J-3). The sedimentassociated mercury levels in Demopolis Lake rose in 1979 from an average of 0.02 mg/kg in 1978 to 0.07 mg/kg in 1979 (Tables J-1 and J-3, respectively). Demopolis Lake was the only river section to show an overall accumulation of sediment-associated mercury during 1979 as compared to the 1978 levels. Most stations showed a marked decrease in 1979, especially the Lower Black Warrior and Tombigbee Rivers.

Cadmium. Levels of sediment-associated cadmium showed a tremendous increase between 1978 and 1979 samplings. The increase was near 1000% on the average and occurred in all river sections. The highest 1978 value was 0.14 mg/kg reported at R-20 (Table J-1); in 1979 the highest reported value came from R-3 and was 2.0 mg/kg. The minimum value in 1978 was 0.01 mg/kg and occurred at R-3 and R-4 (Table J-1); in 1979 the minimum was 0.37 mg/kg at R-10 (Table J-3). Although all sections exhibited these increases, Demopolis Lake had the greatest increase, rising from an average of 0.075 mg/kg in 1978 to 1.0 mg/kg in 1979 (see Tables J-1 and J-3). Thus, all river sections, and virtually all stations, experienced a ten-fold increase in sediment associated cadmium levels during the study period. It should be noted that due to the drastic nature of these increases, all laboratory procedures and calculations were double checked and found to be correct. Additionally. precision and accuracy data show the analyses to be in-control during each sampling and analysis period.

Appropriate Systems (Systems Appropriate Systems)

Nickel. Sediment-associated nickel levels remained unchanged or showed slightly reduced levels at most stations between the 1978 and 1979 samplings, although at least one station in each section showed markedly increased nickel concentrations. Warrior Lake showed increased 1979 levels for nickel at R-1 and R-2 (Table J-3). The average for those two stations in 1978 was approximately 4.5 mg/kg (Table J-1) and was 8.7 mg/kg in 1979 (Table J-3). R-8 showed the highest values in Warrior Lake during both years, with 12.8 mg/kg in 1978 (Table J-1) and 13.0 mg/kg in 1979 (Table J-3). All other stations in Warrior Lake remained approximately equal or showed a slight decline over the study period. In the Lower Black Warrior River, R-12 showed a nearly 100% increase, from 2.5 mg/kg in 1978 (Table J-1) to 4.6 mg/kg in 1979 (Table J-3). The stations in the middle of the section exhibited a decline of at

least 30%. Tombigbee River stations (except R-17 and R-20) exhibited an overall decrease in sediment-associated nickel values (Table J-3). Nickel levels at R-17 increased from the 1978 level of 1.3 mg/kg (Table J-1) to only 13 mg/kg (Table J-3). R-22 in Demopolis Lake showed a marked increase. The 1978 value was 10.5 mg/kg (Table J-1), and the 1979 level was 17 mg/kg (Table J-3). Thus, although most stations evidenced a general decline in levels of sediment-associated nickel, one station in each section indicated an accumulation of nickel.

Zinc. Levels of sediment-associated zinc showed no consistent trend of increase or decrease in most river sections. In Warrior Lake. R-8 had the highest zinc concentrations both years, with 44 mg/kg in 1978 (Table J-1) and 55 mg/kg in 1979 (Table J-3), with the exception of R-2 and R-6 (see Table J-1 and J-3), all other stations maintained near constant concentrations or slightly declined. All stations in the Lower Black Warrior River, except R-12, indicated decreased sedimentassociated zinc levels from 1978 to 1979. During both years the lowest zinc concentrations were found at R-12, immediately below Warrior Lock and Dam, and concentrations steadily rose to reach a high for the section at R-16 (see Tables J-1 and J-3). Values for zinc in the Tombigbee River varied only slightly during the study period at all stations except R-17. At this station the 1978 value was only 4 mg/kg (Table J-1), but it increased to 23 mg/kg in 1979 (Table J-3). A similar rise was seen at R-22 in Demopolis Lake which was 37 mg/kg in 1978 (Table J-1) and 63 mg/kg in 1979 (Table J-3), the highest zinc level observed in 1979. The results indicate only minor changes in zinc sediment concentration over the entire study area during the one year period of observation.

Arsenic. Arsenic showed a pattern of increases similar to that of cadmium, with the average being a five- to ten-fold increase between 1978 and 1979. Warrior Lake showed the greatest consistent increases from 1978 to 1979. The 1978 high for sediment-associated arsenic in this section was 0.82 mg/kg at R-8 (Table J-1); the 1979 high was 8.7 mg/kgat R-9 (Table J-3). This level of increase is typical for the section. The Lower Black Warrior River generally had smaller arsenic levels with 0.80 mg/kg as the high in 1978 (Table J-1) and 7.2 mg/kg (Table J-3) in 1979. The magnitude of increase from 1978 to 1979 was approximately the same as in Warrior Lake but the overall 1979 levels were lower (Table J-3). The Tombiquee River showed the overall lowest levels of sedimentassociated arsenic in both samplings. Also, during both 1978 and 1979 arsenic showed a steady downstream increase. In 1978, R-17 in the upper reaches of the Tombigbee River had 0.14 mg/kg arsenic (Table J-1) and in 1979 this station had 2.6 mg/kg (Table J-3). This level rose to 0.74 mg/kg in 1978 and 10.2 mg/kg in 1979 at the lower reach of the river (Table J-1 and J-3, respectively). Also, the 1979 high level for sediment-associated arsenic was 10.2 mg/kg. Demopolis Lake also showed the ten-fold accumulation of arsenic having a 1978 average of 0.76 mg/kg (Table J-1) and a 1979 average of 8.5 mg/kg. This 1100% increase was the greatest for any river section. Thus, levels of sediment-associated arsenic showed increases in the one-year study period averaging about ten-fold. This increase was very similar to the increases exhibited by sediment-associated cadmium.

Chromium. Levels of sediment-associated chromium showed general increases during the study period of approximately 100%. During both studies the highest levels of the chromium were found in Demopolis Lake.

The 1978 high was 17.9 mg/kg at R-22 (Table J-1), and the 1979 high also occurred at R-22 and was 34 mg/kg (Table J-3). Warrior Lake had moderate values during 1978, averaging about 5 mg/kg (Table J-1) chromium. These levels were increased in 1979 with the average being approximately 11 mg/kg (Table J-3). R-12, immediately below Warrior Lock and Dam, had the lowest chromium measurements on the Black Warrior River each year. However, the remainder of this section had chromium levels higher than or near the median, as compared to all stations. This was true for the Lower Black Warrior River during both 1978 and 1979 samplings. The Tombigbee River had higher levels than the Black Warrior during both years (Tables J-1 and J-3) with high levels occurring at R-20 and R-21 during 1979 (26 mg/kg and 29 mg/kg, Tables J-1 and J-3, respectively). These results indicate that during the one year study period chromium levels in sediment underwent an approximately doubling in concentration within each river section.

## **Pesticides**

The sediment samples obtained during the 1978 sampling were subjected to a screening and quantification analysis for 15 common chlorinated hydrocarbons and 3 PCB compounds. In these tests only seven compounds were present in detectable amounts (see Table J-2). BHC-Alpha was detected at R-19 and R-20 at 0.3  $\mu$ g/kg and 0.4  $\mu$ g/kg, respectively. BHC-Beta was the most prevalent. The high value, 4.5  $\mu$ g/kg, occurred at R-1. BHC-Gamma (Lindane) was detected at the same stations at concentrations of 2.2 and 2.1 µg/kg, respectively. Heptachlor epoxide showed detectable residue at R-13 and R-24. (1.5  $\mu$ g/kg and 1.0  $\mu$ g/kg, respectively.) Dieldrin was also distributed at these stations with R-13 having 2.0  $\mu g/kg$  and R-14 having 1.0  $\mu$ g/kg. The latter Dieldrin value also occurred at R-16. o,p'-DDT was detected at R-1 and R-12 at concentrations of 8.5 and 12.0  $\mu$ g/kg, respectively. p-p' DDE, was detected at 1.0  $\mu$ g/kg at R-12. Thus, pesticide in sediments analyses showed only patchy distribution of selected compounds. The most prevalent occurrence of detected amounts of chlorinated hydrocarbons was between R-12 and R-16 on the Lower Black Warrior River.

## 3.2 Biological

The results of microbiological, plankton, benthological and aquatic macrophyte studies are presented in this section. Selected data have been summarized and/or presented graphically in this section. Raw data from the monthly collections can be found in the Appendices.

The section dealing with microbiological and associated parameters has been sub-divided into river sections which agree with those described in Section 3.1. In Sections 3.2.2 through 3.2.4, these river segmentations have been slightly revised as explained in those sections.

In addition to these sections, 3.2.5 presents the results of three Algal Growth Potential (AGP) tests. This section is not summarized by river section due to the testing procedure (see 2.2.6). The final section presents the results of the aquatic macrophyte survey, which considers only the river basins and Demopolis Lake as study subdivisions. Thus, the resentation of biological data has been defined on the basis of systematic differences in various river reaches. The varying presentations, which are complete in each section, are used to highlight these differences.

## 3.2.1 Microbiological and Associated Parameters

## Adenosine Triphosphate

Levels of adenosine triphosphate (ATP) showed extreme seasonal fluctuations, but were relatively equal in average distribution throughout the study area. It should be noted that analysis of this data is rendered somewhat incomplete because of the missing data from May and June 1979 (Tables A-5 and A-6).

The highest average ATP value was 56 ng/l which occurred at R-5 (Table 3-20). The lowest average value was 10 ng/l which occurred at R-10 (Table 3-21). 300 ng/l was the highest single ATP value obtained and was recorded at R-9 in October 1979 (Table A-10). ATP levels below detectable quantities (50 ng/l in 1978 and 10 ng/l in 1979) occurred at all stations on several occassions. December 1978 (Table A-4) and February 1979 (Table A-5) had all stations recording non-detectable ATP levels. The overall highest levels of ATP occurred in October 1979 (Table A-10).

Warrior Lake and Demopolis Lake had equal study averages, 33 ng/l (Tables 3-20 and 3-23, respectively). The Tombigbee River had a marginally lower average concentration of ATP, 31 ng/l (Table 3-22). The Lower Black Warrior River had the minimum average, 27 ng/l (Tuble 3-21). Although there was a slight sectional differentation, the season fluctuation (<10-300 ng/l) was much greater.

## Chlorophyll a, b, c

Active chlorophyll  $\alpha$  (chlorophyll  $\alpha$  corrected for pheophytin) showed large seasonal variations with only minor variations in average values for the river sections. Chlorophyll b and c were also measured by the trichromatic technique. However, a growing body of literature disputing the validity of these estimates has indicated that these data are best left in raw form as given in Appendix A. The literature suggests that estimates of chlorophyll b and c are in error up to 75% when produced by the trichromatic method (Trotter and Hendriks, 1979)

Chlorophyll  $\alpha$  had a maximum average of 15 µg/l which occurred at R-20 (Table 3-22). The minimum average was 2 µg/l, which was recorded at R-1 (Table 3-20). The single highest concentration of chlorophyll  $\alpha$ , 41 µg/l, occurred at R-20 during late August 1979 (Table A-9). The minimum chlorophyll  $\alpha$  value detected was <1 µg/l, which was recorded at several stations during December 1978 (Table A-4). Generally, the lowest levels of chlorophyll  $\alpha$  were observed during December 1978 (Table A-4) and the highest levels during July 1978 (Table A-1).

The Tombigbee River had the maximum average chlorophyll  $\alpha$  levels during the study period, 10  $\mu$ g/l (Table 3-22). Demopolis Lake and the Lower Black Warrior had slightly lower average values, 8  $\mu$ g/l each (Tables 3-23 and 3-21, respectively). The minimum average level of chlorophyll  $\alpha$ , 7  $\mu$ g/l, was recorded for the Warrior Lake (Table 3-20). These river section differences are minor. The major variation for chlorophyll  $\alpha$  occurred seasonally.

#### Dissolved Organic Carbon

Levels of dissolved organic carbon (DOC) evidenced strong seasonal and river sectional trends. R-20 had the highest average DOC, 8.1 mg/l (Table 3-22). The lowest average concentration of DOC was 3.0 mg/l, recorded at R-5 (Table 3-20). R-17 recorded the maximum level of DOC, 21.6 mg/l, in August 1978 (Table A-2). Non-detectable levels, <2.0 mg/l, occurred at all stations in June 1979 (Table A-7). This was overall lowest month for DOC levels. The highest overall levels occurred in October 1978 (Table A-3).

The Tombigbee River had the highest overall average DOC concentrations, 7.4 mg/l (Table 3-22). Warrior Lake had a study period average of 4.1 mg/l (Table 3-20), the lowest average of all sections. The Lower Black Warrior River had a moderately higher level, 4.5 mg/l (Table 3-21). Demopolis Lake had an intermediate average DOC level, 5.7 mg/l (Table 3-23). Thus, there were some moderate section variations in DOC, but seasonal fluctuations were much larger.

## Total Organic Carbon

Total organic carbon (TOC) roughly paralleled the seasonal and sectional trends for dissolved organic carbon, with only slightly higher average levels in most river sections. The highest level of TOC recorded was 9.5 mg/l which occurred at R-19 and R-20 (Table 3-22). The lowest level was 3.8 mg/l which occurred at R-9 (Table 3-20). The maximum concentration observed during the study was 19.0 mg/l at R-18 in February 1979 (Table A-5). Non-detectable TOC values (<2 mg/l) were recorded at all stations in June 1979 (Table A-7). This represented the overall lowest month for TOC. Generally, the highest TOC concentrations occurred in October 1978 (Table A-3).

#### Fecal Coliform

Main River Stations. Levels of fecal coliform bacteria (FC) were quite variable, both seasonally and by river sections. R-1 had the highest average FC concentration, 1061 (Table 3-20; all values are as number per 100 milliliters). The lowest average FC concentration was 11, which occurred at R-16 (Table 3-21). The single highest numerical value recorded was 4380 at R-20 in May 1979 (Table A-6). Note that R-13 through R-15 had levels "too numerous to count" in October, 1978 (Table A-3), although this is not indicative of numbers higher than the maximum value stated above. The minimum level of FC recorded, <1, occurred at several stations during July 1978 (Table A-1), August 1978 (Table A-2) and October 1978 (Table A-3). Generally, the highest fecal coliform levels were observed in May 1979 (Table A-6); the lowest levels were observed in August 1978 (Table A-2).

Warrior Lake, especially R-1 and R-2, showed high average values. The river section average was 346 (Table 3-20). This value was very much reduced in the Lower Black Warrior River, with the study period average being only 53 (Table 3-21). The Tombigbee River had the overall highest average value, 418 (Table 3-22). Demopolis Lake had moderately high FC levels, with an average of 275 (Table 3-23). Thus, both seasons and river sections produced large variations in FC levels.

<u>Bacteriological Stations</u>. The results of FC analyses at bacteriological stations C-1 through C-4 are presented in Appendix K. Station

C-4 typically had the highest values with a study average of 493 and a range of 1 to 3700. C-2 had the lowest values with a study average of 46 and a range of 0 to 373. C-1 and C-3 had intermediate averages, 67 and 50 respectively. C-1, C-2 and C-3 had their maximum levels in February 1979, C-4 had a maximum in October 1979.

#### Fecal Streptococci

Main River Stations. As with FC levels, concentrations of fecal streptococci (FS) showed large seasonal and river section variations, R-19 (Table 3-22) had the highest average FS level, 632 (all values represent number per 100 millimeters). The lowest average level of FS, 62, occurred at R-14 (Table 3-21). The FS maximum, 3950, occurred at R-13 during July 1979 (Table A-8). The minimum value was <1 which occurred at several stations in various months, primarily July and August 1978 (Tables A-1 and A-2, respectively). Generally, the highest values occurred in July 1979 (Table A-8) and the lowest during August 1978 (Table A-2).

The Tombigbee River had the overall highest FS values, 450 (Table 3-22). Warrior Lake, with a study period average of 127 (Table 3-20), had the overall lowest FS levels. The Lower Black Warrior River was moderately higher, 183 (Table 3-21). Demopolis Lake had an intermediate average, 285 (Table 3-23). These results indicate that both seasonal factors and river basin characteristics caused FS levels to be widely varied.

Bacteriological Stations. Station C-2 and C-4 had the greatest average FS levels, 159 and 204 respectively (Table K-1). The other two stations had study period averages of approximately 100. C-1 through C-3 showed the highest levels in February 1979. C-4 had its highest FS level, 930, in October 1979. The maximum value, 1040, occurred at C-2 during this month.

#### FC:FS Ratio

Main River Stations. Average FC:FS ratios (herinafter referred to as ratios) have been calculated in Tables 3-20 through 3-23 based on average FC and FS levels as given on the same tables. Although slightly different averages result from the arithmatic mean of the monthly ratios, the ratios in these tables are useful in locating trends of this calculated parameter. The highest ratio was 6.9, occurring at R-2 (Table 3-20), which indicates high levels of fecal coliforms as compared to fecal streptococci. The lowest calculated ratio, 0.1, occurred at R-13 and R-16 (Table 3-21), indicates higher fecal streptococci at these stations. Warrior Lake had a section average of 2.7, the Lower Black Warrior River had a ratio of 0.2 for an average. The Tombigbee River had nearly equal levels of FC and FS, with a study period ratio of 0.9. Lake Demopolis had the same result, with an average ratio of 1.0. These results indicate tremendous variation between stations in relative FC and FS loadings.

Seasonally, the highest ratios occurred in December 1978 (Table A-4) and the lowest occurred in August 1978 (Table A-2) when all ratios were calculated as <1.0. The highest ratio was 153, which occurred at R-1 in July 1978. These results indicate a moderate seasonal fluctua-

tion which does not effect the trend of FC:FS loading at any one station or river section.

Bacteriological Stations. All bacteriological stations showed a predominance of ratios greater than 1.0, with a maximum of >25 at C-3 and C-4 in September 1978 (Table K-1). In June and July 1979, all stations showed ratios less than 1.0, which by August 1979 had gone over 1.0 again. These results generally indicate FC loadings in tremendous excess over FS loadings.

#### 3.2.2 Phytoplankton

The designation of river basin sections has been revised for presentation of the remaining biological results. These new designations generally reflect environmental changes (Depth, current velocity) which affect biological communities. To facilitate reading this presentation the following summary is presented:

Stations	Section Designation
R-1 to R-5	Upper Warrior Lake
R-6 to R-10	Lower Warrior Lake
R-12 to R-16	Lower Black Warrior River
R-17 to R-21	Tombigbee River
R-22 to R-23	Demopolis Lake

Results of the monthly collections of phytoplankton are found in Appendix L. The tables of this appendix list all taxa identified and the number per milliliter. These data have been reduced to the tables and the figure in this section.

Table 3-24 is a complete listing of all algal taxa identified during the course of the study. The algae represent 200 genera and species divided among the five major divisions. The Chlorophyta (green algae) accounted for 55% of the total number of taxa identified. In rank order the remaining divisions were Chrysophyta (yellow green algae, primarily diatoms), 29%; Cyanophyta (blue green algae), 9%; Euglenophyta (euglenoids), 6%; and Pyrrophyta (dinoflagellates), 1%.

The green algae were overwhelmingly represented by the members of the Oöcystaceae and the Scenedesmaceae. These, with the remaining members of the Chlorococcales, accounted for approximately 80% of all green algae. Species from the other represented orders generally accounted for low numbers throughout the study (see Appendix L). The yellow green algae were represented predominantly by diatoms (Ophiocytium and Dinobryon being the exceptions). Most diatom species found were pennate forms; however, centric forms often accounted for large numbers (Appendix L). The blue greens were mainly represented by filamentous forms with only three coccoid genera being identified. Taxonomy of these groups is taken from the revisions of Drouet and Daily (1956) and Drouet (1967, 1976 and 1978), thus, yielding short taxa list for blue green forms. Thus, the green algae had the over-

Table 3-24. Phylogentic Listing of all Algal Taxa Encountered, Middle Black Warrior and Tombigbee Rivers, July 1978 through October 1979.

all highest number of taxa identified with diatoms and blue greens contributing moderate percentages. However, the majority of taxa identified did not reflect dominance in terms of numbers or frequently even community composition.

-3.35

Figure 3-1 presents a monthly comparison of community compositions and total numbers by river sections. The Black Warrior River (all sections) had a phytoplankton community almost wholly composed of diatoms between July 1978 and May 1979. During this period Warrior Lake had the highest numbers of phytoplankton of any river section. An exception to this occurred in October 1978 when the blue green algae contributed 75% to the Upper Warrior Lake and that section had the highest total number of phytoplankton of all sections. During this same six-month period the Tombigbee River and Demopolis Lake had trends different from the Black Warrior River that were not as consistent as those for the Black Warrior River.

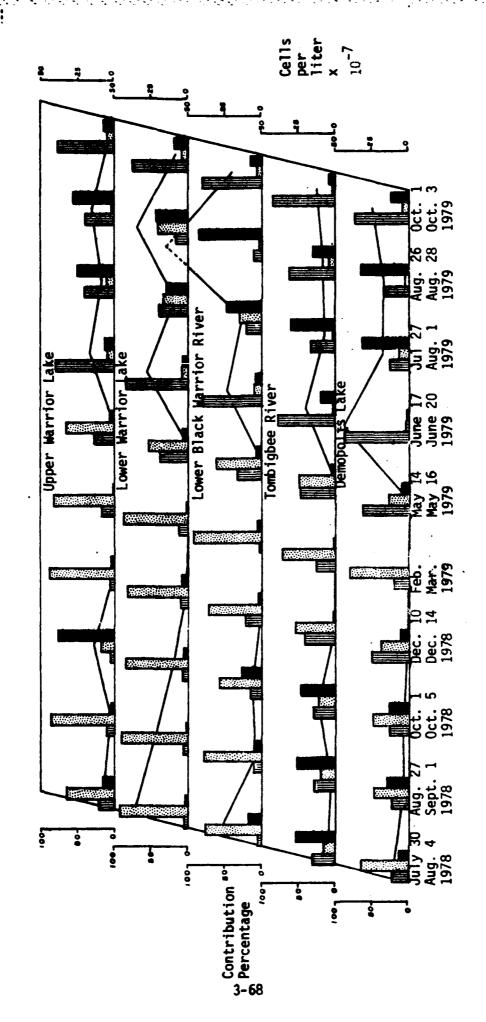

During July through October 1978, the Tombigbee River phytoplankton community was primarily composed of blue green algae, although the other divisions were well represented. In December 1978 the composition dramatically changed with blue greens essentially disappearing and diatoms assuming the major portion of the phytoplankton community. Demopolis Lake phytoplankton, in contrast to the other sections, was relatively evenly distributed among the principal orders between July and December 1978. This trend ended with the February 1979 collection which had 80% diatoms. Another major composition change occurred in the Demopolis Lake phytoplankton community in May 1979 when the green algae contributed 60% of the phytoplankton. This was the only section with a majority of green algae during the first half of the study.

During the second half of the study, phytoplankton populations went through a series of community shifts. In June 1979 all sections were composed primarily of green algae, which was almost wholly represented by Ankistrodesmus convolutus (Table L-7). Additionally, total numbers of algae rose from very low levels to moderately high to very high levels, especially in the Tombigbee River and Demopolis which had their highest total numbers for the study (2.3x10<sup>8</sup> and 4.8x108 cells/liter, respectively). This early summer community was quickly replaced with blue green algae becoming dominant in July, 1979 in most sections. All sections experienced a drop in total numbers of phytoplankton during this month. August 1979 continued in this pattern, with the blue greens remaining the largest percentage group in most sections (the Tombigbee River had a higher green algae component). Warrior Lake and the Lower Black Warrior River had maximum phytoplankton levels during this month with 3.5x10<sup>8</sup> and 7.2x10<sup>8</sup> cells/liter respectively. October 1979 had a decrease of blue green algae to 10-25% in all sections with the greens rising to >75%. Total numbers had moderately declining values in all sections.

obsolite Difficulty Consistent Additional Additional District Consumer Des

These results demonstrate that most sections of the study area have strong seasonal variations in algal assemblages, but these variations do not repeat from year to year. An assessment of the dominant algal species (as defined by the two species contributing the first and second largest number of cells during each collection), reveals a similar pattern of change as the community composition charts (Figure 3-1). Table 3-25 lists the total number of stations during each collection at which a given species was a dominant, either first or second

Community Composition and Total Numbers of Phytoplankton in Major River Sections, Middle Black Warrior and Tombigbee River, July 1978 thru October 1979. FIGURE 3-1.

Contribution Percentage Legend:

Chlorophyta Chrysophyta

Cyanophyta Total Number

Trips 1 through 5 (June 1978 through May 1979) were primarily dominated by diatoms (Figure 3-1). These diatoms were the centric, chain forming species Melovira granulata, M. distant and Cyclotella glomerata (Table 3-25). It can also be seen that the occasional high percentage of blue green algae during these months was due almost entirely to the coccoid colonial Agmenellum quadriduplicatum (Merismopedia punctata). The occurrence of several benthic diatoms (Nitzschia spp., Navicula cryptocephala and Stauroneis spp.) was interesting in the light of extremely low numbers of phytoplankton during Trip 5. February 1979 (Table L-5). As noted above, the shift to the green algae as a percentage contribution dominant was caused by a bloom of Ankistrodesmus convolutus during Trip 7, June 1979. The summer levels of blue green in 1979 were once again attributed to Agmenellum auadriduplicatum, with occasional occurrences of high levels of Oscillatoria (R-4, R-16 through R-20, July 1979, Table L-8) and Anabaenopsis circularis (R-21, July 1979, Table L-8). The green algae dominance during Trip 10, October, 1979, was again due to Ankistrodesmus convolutus, although with much lower total numbers than the spring bloom (Table L-10).

In summary, phytoplankton communities during the study period showed summer maxima (June 1978 and June/August 1979) with diatoms being the major component in 1978 and greens in 1979. Lowest total numbers were observed in the winter and early spring (December 1978 through May 1979). Although many species were occasionally abundant, those algae which showed the dominant position were quite consistent. The blue green coccoid Agmenellum was the most frequent dominant with centric, chain forming diatoms, Melosira and Cyclotella glomerata being the most common. Ankistrodesmus convolutus accounted for 60% of the occurrences of green algal dominances, and twelve other species made up the remaining 40% of the green algal dominance. Phytoplankton numbers in the Upper Warrior Lake and the Tombigbee River were relatively low in each collection. Lower Warrior Lake had the most consistent high levels of phytoplankton, with Demopolis Lake having levels in late 1979 about tenfold as high as numbers during the same period of 1978. The Lower Black Warrior River had the overall study period maximum for phytoplankton numbers in August 1979. Thus, for phytoplankton trends in the Middle Black Warrior and Tome thee Rivers. the marked shift in dominance and total numbers patterns Latween May and June 1979 which did not return to the trends of the summer and autumn of 1978 was the most significant observation for this study.

# 3.2.3 Zooplankton

(NOTE: River basin sections are as described in Section 3.2.2).

Results of monthly collections of zooplankton are found in Appendix M. The tables in this appendix list all taxa identified and the number of organisms per liter. This data has been reduced to the tables and the figure in this section.

Table 3-26 is a complete listing of all zooplankton taxa identified during the course of the study. The list represents 68 genera and species divided over three phyla: Protozoa, Rotifera and Arthropoda. The latter phylum has two major classes represented in these collections: Cladocera and Copepeda. The Rotifera (rotifers) accounted for the of

the species identified, the single largest contribution. The remaining phyla and classes were rank ordered as Cladocera (cladocerans), 18%; Protozoa (protozoans), 16%; and Copepoda (copdpods), 6%. The largest group, the rotifers, were divided among two orders and twelve families. The most abundant family was the Brachionidae. The Daphididae was the most abundant cladoceran family and the copepods were relatively evenly divided among the identified groups. The Protozoa genera and species encountered cover many subphyla and classes. However, generic distribution among these major taxa is relatively even. The distribution of numbers of species among the major taxa is very representative of the patterns of dominance in the zooplankton community structure.

Figure 3-2 is a summary of the community composition of zooplankton during the monthly collections. The most obvious feature of the zooplankton community structure is the predominance of rotifers in the majority of collections. During the first three collections of the study, June to October 1978, rotifers were the dominant group in all but two instances. In June 1978 copepod naupli were about 5% greater in occurrence in Upper Warrior take. Indeed, during all trips in this period the percentage contribution of copepods was higher in Upper Warrior Lake than any other section. In August 1978, the cladocerans were slightly more abundant than the rotifers in Lower Warrior Lake. Cladocerans also contributed fairly high percentages to the community structure in the Lower Black Warrior River and Demopolis Lake. All sections showed moderately high total numbers (>200/liter) during the early summer, with a steady decline during late fall. These summer communities began to shift during the first winter collection.

Winter zooplankton collections, December 1978 and February 1979, were more evenly composed of all major groups. Upper Warrior Lake samples during the winter were dominated by copepods, with protozoans having about 10% of the compositions. Lower Warrior Lake had a community structure of about the same distribution. Both of these sections also had relatively high proportions of cladocerans (25%). The Lower Black Warrior River had fewer copepods (20%) with rotifers and cladocerans having about 40% each during December 1978. In the Tombigbee River and Demopolis Lake, rotifers and copepods were the major groups in December. During February 1979, all river sections were dominated by copepods, including many adult forms, with rotifers having moderately high percentages as well. From these relatively even distributions in the winter, which were accompanied by very low numbers (10-50 per liter), early spring zooplankton populations showed marked increases.

Throughout the remainder of the study, including spring, summer and early fall 1979, rotifers were generally the dominant group of organisms. Only the Upper Warrior Lake showed variation from this trend, having copepod nauplii and adults as a major contributor in June and July 1979. Maximum numbers of zooplankton were recorded in June 1979, especially in Lower Warrior Lake (600/liter), the Lower Black Warrior River (700/liter) and Demopolis Lake (450/liter). Upper Warrior Lake and the Tombigbee River did not exhibit these large numbers in June 1974 but had only moderate total numbers (200-300/liter) which were comparable with numbers observed throughout the warm months. All stations experienced a decline in total numbers in July 1979 (e.g. Lower Warrior Lake dropped from 600/liter to approximately 150/liter),

Community Composition and Total Numbers of Zooplankton in Major River Sections, Middle Black Warrior and Tombigbee Rivers, July 1978 and October 1979 FIGURE 3-2.

although rotifers remained the predominant organism. Proughout the remainder of the study, rotifers dominated the collections although copepods began to increase in most sections in August 1979 while cladocerans had a 1979 peak (30% contribution) in Demopolis Lake during August 1979. In all cases, rotifers were the spring to fall dominant in all river sections in 1979 with the average contribution being approximately 90%.

The dominance of the rotifers in percentage contribution was reflected in the analysis of dominant species (defined as the two most numerically abundant species at each station during each collection). Fu'ly 70% of organisms recorded as dominant were rotifers (Table 3-27) with Keratella cochlearis at spp. being dominant at 18% of all samples collected. Conochilus unicormis, a ubiquitous rotifer, was dominant in 15% of the samples. The only non-rotifer contributing more than 5% dominants to the total study was the cladoceran Bosmina longirostris, with 12% total dominance. Three protozoans, Ceratium hirudinella, Epistylus nigare and Vorticella sp., were occasional dominants, as were the copepods Cyclops spp and Diaptomus spp. Rotifera was the most abundant phylum with the Cladocera, Copepods and Protozoa following in rank order.

In summary, zooplankton populations evidenced summer maxima and winter minima with rotifers comprising both the greatest number of taxa encountered and the highest levels of dominance, both by percent contribution and numerical abundance. The cladocerans, especially Bosmina longirostris, were frequently abundant in mid-summer while copepods showed high percentages in community contribution in the late fall and winter months. As with phytoplankton (see Section 3.2.2), a marked change was noted in spring 1979 (May) when the percentage of rotifers far exceeded the community contribution of the Rotifera in 1978. In but a few instances, the contribution of the Crustacea was quite low during all of 1979.

# 3.2.4 Macroinvertebrates

# 3.2.4.1 Benthic Macroinvertebrates, Ponar Dredge

Collections of benthic macroinvertebrates were made at three points of the river cross section at each station. The results of these collections and the averages and calculated indices are found tabulated in Appendix N. The summarization of this section presents a listing of taxa identified and river section versus date data for community composition, total numbers and Shannon-Weaver diversity.

Table 3-28 is a complete listing of all benthic macroinvertebrates collected by Ponar dredge during the study. Class Insecta provided the greatest number of species with Chironomidae (chironomids, the midgeflies) having the greatest number of taxa (genera) of any family. Other insect groups, rank ordered by number of taxa in each, are the Ephemeroptera (mayflies), the Trichoptera (caddisflies), Coleoptera (beetles), Odonata (dragon and damselflies), Plecoptera (stoneflies) and Megalortera (fishflies). Many other phyla and classes were represented. Of these, many were of only occasional occurrence. For this reason, many organisms were of only minor importance to the community structure. To facilitate interpretation of data, many of the less prevalent taxa have been grouped together.

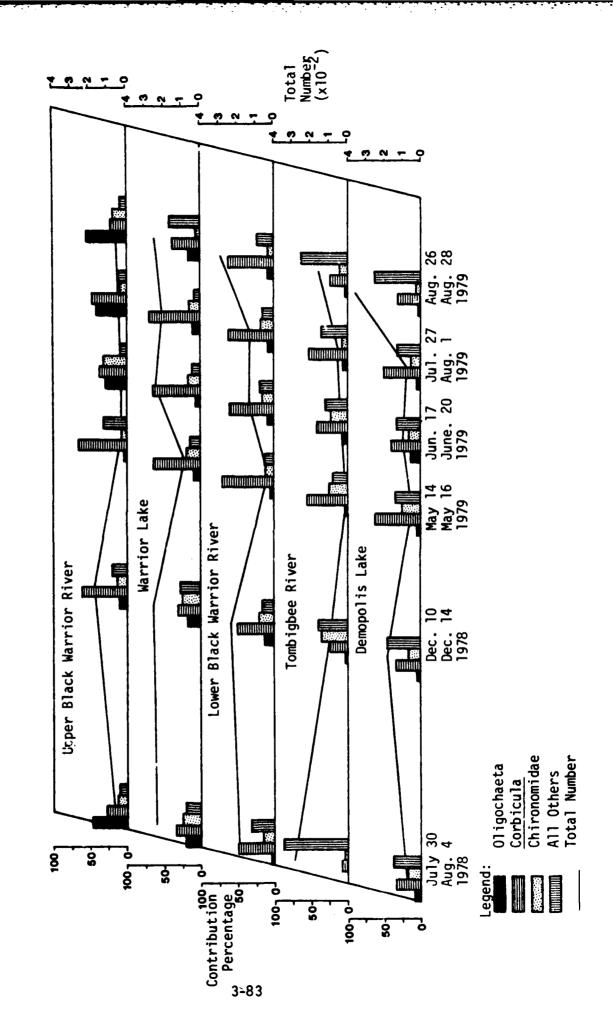

Figure 3-3 presents a graphic representation of the major benthic macroinvertebrate groups as they comprised the benthic community. Additionally, the graph displays total numbers of benthic macroinvertebrates during each month. In most collections the Oligochaeta comprised >50% of the total community structure. However, several exceptions are noted. The Warrior Lake was frequently dominated by Corbicula manilensis. This was the case during the summer of both 1978 (July 1978, Table N-1) and 1979 (August 1979, Table N-6). In the 1978 collection, many clams were large but during 1979 all clams were less than 0.5 cm in diameter (see tables given above). Lower Warrior Lake also had moderate numbers of Corbicula, with the average percentage contribution being about half that of Upper Warrior Lake (Figure 3-3). The Lower Warrior Lake clams were generally larger than those found in Upper Warrior Lake as evidenced by biomass estimations (Table 3-4). The group listed as "All others" in Figure 3-3 was generally comprised of mayflies and caddisflies. This group was an occasional majority of the benthos. The Tombigbee River and Demopolis Lake had the highest overall contributions of this grouping. The Tombigbee River was 90% "others" in July 1978 of which 75% was contributed by Chaborus and 25% by the mayfly \*\*magenia (Table N-1). Another peak of "others" occurred in the Tombigbee River in August 1979 was also contributed by the mayflies (Table N-6). Mayflies, especially large Hexagenia, were also responsible for the parallel peaks in Demopolis Lake (Table N-1 and N-6). The chironomids were a ubiquitos and evenly dispersed group, occurring in all sections as at least 10-25% of the benthos.

Trends of total numbers (Figure 3-3) and biomass (Figure 3-4) show very similar patterns. A maxima occurred in December 1978 for all Black Warrior River sections with Lower Warrior Lake having the highest average total number of benthos,  $350/m^2$  (Figure 3-4). The highest non-Gorbicula biomass occurred in Lower Warrior Lake in July 1978, 16 g/m², and was largely comprised of large Hexagenia. All sections, except Demopolis Lake, experienced a sharp decline in numbers and biomass during May 1979. The high biomass in Demopolis Lakes during that month was predominantly Hexagenia in conjunction with the chironomids (Table N-3). During the summer month of 1979, a total number of benthos increased steadily, reaching a maximum in all sections in August. Biomass values however, were low (>5.0 g/m²) throughout this time. In general, however, Warrior and Demopolis Lakes had the highest total numbers and highest average biomasses of any of the river sections.

Shannon-Weaver diversity values  $(\overline{d})$  are given, along with section, monthly and study period averages in Table 3-29. Generally, all stations showed  $\overline{d}$  values in the range defined by most workers as indicative of "intermediate water quality" (Mason, Lewis and Hudson, 1975). Although slight fluctuations in average values for the river sections are present (1.75 to 2.35), the basic pattern of benthos diversity is not varied from river section to river section. The major noticeable trend across the months is the distinct drop in  $\overline{d}$  levels between December 1978 and May 1979 in all sections (May 1979 had the lowest average  $\overline{d}$  during the study).

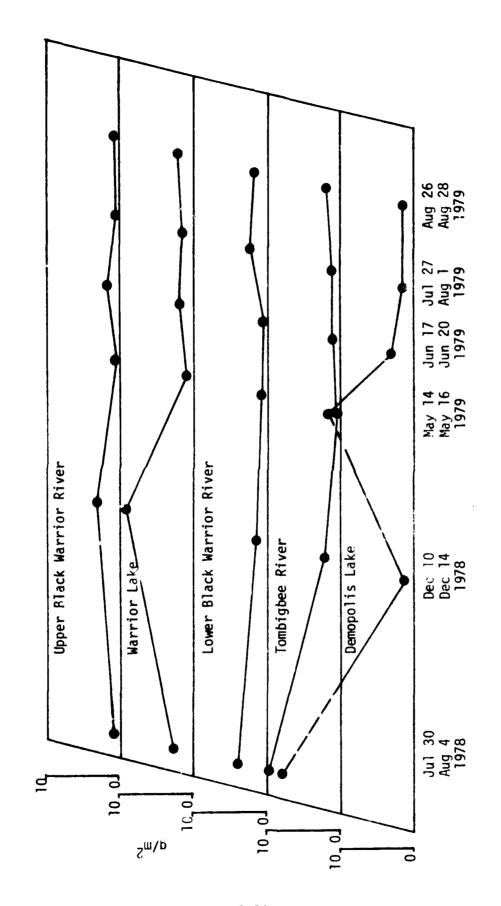

In summary, the Middle Black Warrior and Tombigbee River system benthos is comprised chiefly of insects and oligochaetes and shows wide seasonal variations of benthic biomass. Lower Warrior Lake and Demopolis Lake had the highest total numbers and biomass values.

Percentage Contribution of Selected Taxa and Total Numbers of Benthic Macroinvertebrates, Middle Black Warrior and Tombigbee Rivers, July 1978 thru October 1979 Figure 3-3.

A CONTRACTOR OF THE PROPERTY O

Collection Date

Shannon-Weaver diversity indicies indicated, on the average, that both river basins were moderately polluted and had only slightly varying species diversity. Overall, the river basins have an abundance of benthic organisms which comprise the basis of the food chain leading to good fish production in the study area.

# 3.2.4.2 Macroinvertebrates, Multiple Plate Samplers

Multiple plate samplers (MPS) were positioned at selected stations during four sampling periods. At several collection dates (see Appendix 0) some samplers were not recovered due to loss by vandalism, high water or other means. Results of these collections are found in Appendix 0. Table 3-30 presents the taxa of macroinvertebrates identified from multiple plate samplers.

The overwhelming majority of invertebrates collected by MPS we're chironomids. Approximately 30% fewer genera were encountered on the MPS than in the benthos collections. August 1978 had very high total numbers of organisms (2000-6000/m²) which were 20% caddisflies (represented by Cyrnellus) and 70-75% chironomids (Table 0-1). The February 1979 collection evidenced a marked decrease in total numbers  $(540-850/m^2)$  although chironomids continued to comprise  $\geq 75\%$  of the community (Table 0-2). Summer 1979 samples showed a return to the levels seen in July 1978. The community structure became more balanced with caddisflies and chironomids each comprising about 40% of the collected organisms (see Tables 0-3 and 0-4). Diversity indices (d) for MPS were very similar to those for Ponar samples, with a classification of "intermediate water quality" (see Section 3.2.4.1). In contrast to Ponar samples, neither community structure nor diversity showed much difference between river basins. Thus, MPS, in many respects corroborated trends observed for benthic macroinvertebrates, especially seasonal trends. However, community structures varied significantly, with chironomids being the dominant MPS taxa.

# 3.2.5 Algal Growth Potential

Algal growth potential (AGP) tests were conducted three times during the study period. The results of the individual cell counts and chemical analyses are found in Appendix P. Figure 3-5 summarizes the results.

The results of AGP testing showed wide variation between the actual algal production values for the three tests. However, the treatments to which the algae responded were generally the same during each test. P N and EDTA + P+N generally gave the highest cell production values. N, EDTA and EDTA+N generally produced values in the range of the control treatments. P gave the highest values of any single nutrient.

There are some station by station variations. R-2 had the lowest cell production levels during each test with EDTA+P+N generally producing the highest levels at that station. Another trend at R-2 is the increase in cell production during each sampling trip. All Black Warrior River stations had approixmately equal cell productions in the individual tests with P+N giving the highest results. R-17 produced the highest numbers of cells during October 1978 and results were very low for all stations.) The complete treatment, EDTA+P+N, produced the greatest number of cells at R-17. R-21 results

were similar to R-17, with slightly reduced cell production values for August 1979. At R-23 the results looked quite similar to the Black Warrior River results.

Thus, AGP test results indicate general phosphorus limitation for both basins. Nitrogen and EDTA additions were seen to increase production even further.

### 3.2.6 Aquatic Macrophyte Distribution

The results of the September, 1978, and August 1979, surveys of aquatic macrophytes are presented in Appendix Q. The tabulated data in this section includes alphabetical lists of all plants observed during each survey and a seperate tabulation of the most abundant species and the other plants at each locality. For the purposes of the data presentation the study area has been sub-divided into three sections: Warrior Lake (R-1 thru R-9), the Lower Black Warrior River (R-10 thru R-16) and the Tombigbee River and Lake Demopolis (R-17 thru R-23).

Table 3-31 presents a complete listing of all the taxa observed and reported as aquatic macrophytes. Among these, only a few would be considered true aquatic macrophytes. These would be cattails (Typha), hornwart (Chara), sedges, rushes, giant cutgrass (Zizaniopsis milacea), alligator weed (Alternanthera philoxeroides) and water willow (Justica americana) and coon-tail (Cerataphyllum). Many of the other listed plants (e.g. Sagittaria, Hisbiscus and Taxodium) are shoreline and wet area associates. The remaining species are those plants found growing along the shoreline, on sandbars and along the sides of sloughs and creeks. The listing in Table 3-31 has re-organized into the alphabetical listing and location tables presented in Appendix Q.

The alphabetical listings of plants observed (Tables Q-1, Q-3, Q-5, Q-7, Q-9 and Q-11) indicate that approximately the same species were observed each year. The major variation between the two observations is the inclusion of several more shoreline associates (e.g. alder, river cane) during 1979. This is attributed to two factors. The first is the experience of the investigator in searching likely areas (sloughs, for example) which contribute more species. The second is the variation in water levels of the reservoirs during the two surveys. Thus, the alphabetical lists provide a reference for the location lists (Q-2, Q-4, Q-6, Q-8, Q-10, and Q-12).

Aquatic macrophytes and associated plants occurred throughout the Black Warrior-Tombigbee basin. As can be seen on the location tables (Appendix Q) most macrophytes grew in patches or strips along the banks. These clumps were confined predominately to water less than five feet deep. Aquatic plants also grew well at creek and slough inlets, often forming dense barriers of matted surface growth. In general the aquatic macrophytes were isolated in these near-shore strips and posed no problem to general river traffic.

The location tables also show that the macrophytes were commonly found in "associations" with only rare cases of individual species occurring at single locations. By far the most common aquatic macrophytes, both by number of locations and number of times as the

most abundant at a location, were the giant cutgrass (Zizanopsis milacea), alligator weed (Alternanthera philoxeroides) and water willow (Justica americana). These plants, along with sedges, rushes, hornwart, coon-tail, arrowhead, grasses and the bald cypress. formed the majority of the observed aquatic macrophytes.

The two surveys, when reviewed as a composite, reveal the major distributions of aquatic macrophytes throughout the basin. As stated previously, the differences which arose between the two surveys originated with the experience of the investigator and the fluctuating water level of the reservoirs. Thus, in Warrior Lake, the 1978 survey showed only twenty-six (26) stands of aquatic macrophytes with alligator weed and giant cutgrass predominating (Table Q-2). The 1979 survey of the same reservoir resulted in location of one hundred two (102) stands of macrophytes. The primary difference arose from the definition of Panicum agrostoides and "Association I" (see Table Q-7) as a group of aquatic plants. The majority of the major aquatic macrophytes in Warrior Lake occurred between river miles 296 and 261 during both years (Tables Q-2 and Q-8).

Aquatic macrophyte occurrence in the Tombigbee River and Demopolis Lake was not similar to that observed in Warrior Lake. The Tombigbee River and Demopolis Lake macrophytes were most commonly dominated by stands of water willow (Tables Q-6 and Q-12). Giant cutgrass, alligator weed and marsh primrose were essentially absent from the Tombigbee River. Alligator weed began to show scattered distribution about river mile 231 (Tables Q-6 and Q-12) and continued to increase in abundance on into Demopolis Lake. Specific locations for alligator weed and giant cutgrass were quite similar during the 1978 and 1979 surveys. The habitats were littoral zones, creek mouths and sloughs, similar to the habitats occupied by these plants.

Figures 3-6 through 3-12 show the distributions of the major aquatic macrophytes discussed above. The location indicators (dots) should be taken to reference an observation of the listed species along that stretch of river. These figures should be compared to the location charts in Appendix Q for details on the exact location and areal extent. Further attention should be given to the plants associated with the major macrophytes given in the figures.

Figure 3-6 illustrates the distribution of alligator weed in the Middle Black Warrior-Tombigbee Basin. The plant is throughly scattered along the Black Warrior River, but is confined to Demopolis Lake and Rattlesnake Bend on the Tombigbee River. An isolated patch was observed near Epes, which may indicate the beginnings of upstream migration in the Tombigbee River. Giant cutgrass (Figure 3-7) showed the same general distribution as alligator weed, although the cutgrass had significant stands (see Appendix Q) as far upstream as Oliver Lock and Dam on the Black Warrior River.

The Tombigbee River had stands of water willow (Figure 3-8) extending much farther upstream than occurred on the Black Warrior River. However, both Warrior Lake and Demopolis Lake had the greatest concentration of water willow, with a less dense distribution being observed farther upstream.

Figure 3-6. Distribution of Alligator Weed (Alternanthera philoxeroides), Middle Black Warrior and Tombigbee Rivers, September 1978 and August 1979.

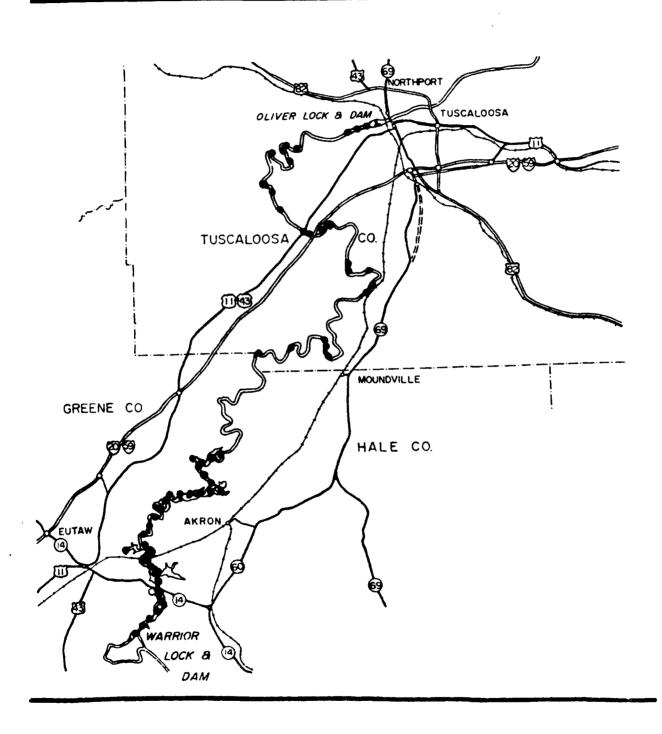

Figure 3-7. continued

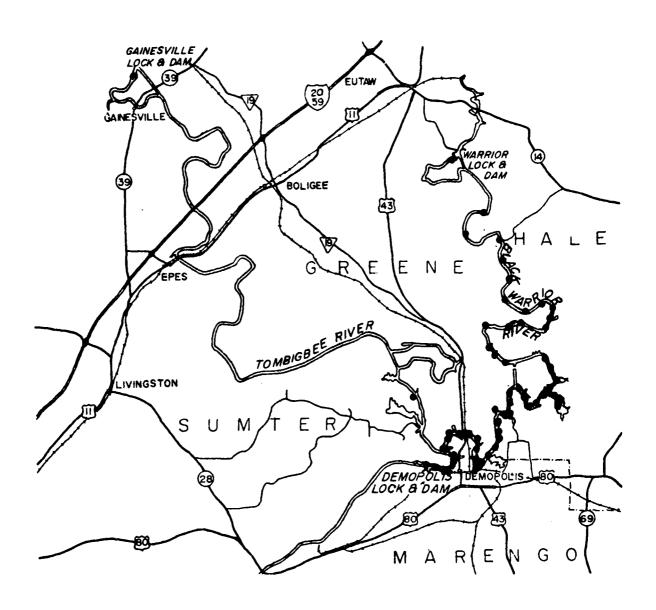

Figure 3-8. Locations of Water Willow (Justica americana), Middle Black Warrior and Tombigbee Rivers, September 1978 and August 1979

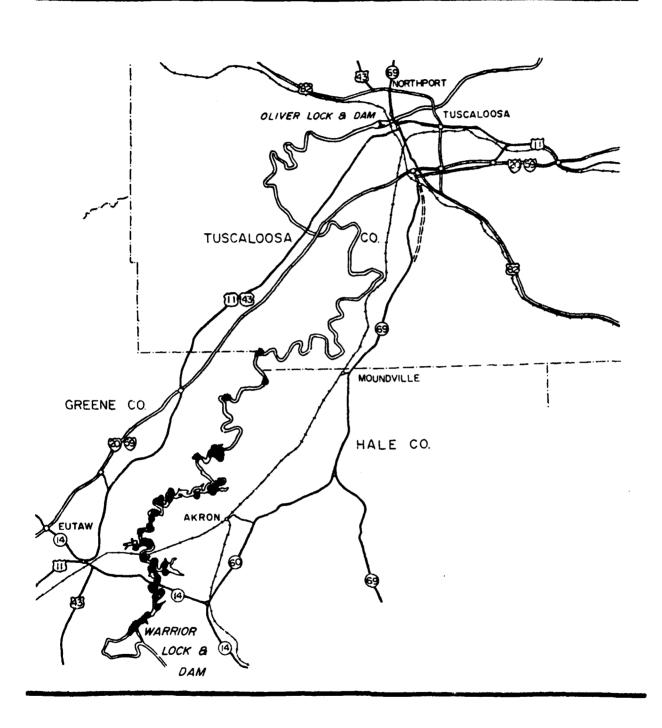

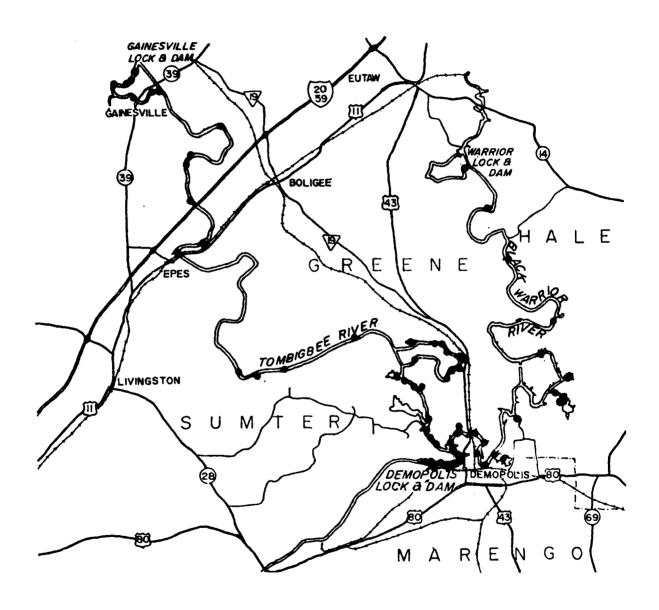

Figure 3-8. continued

Figures 3-9 through 3-12 show the locations of some of the aquatic macrophytes with limited distribution. Coon-tail (Figure 3-9) and hornwort (the macrophytic alga *Chara*, Figure 3-10) were restricted to Warrior Lake immediately upstream of the dam. Water primrose (Figure 3-11) showed some minor stands (see Appendix Q) throughout Warrior Lake. The *Panicum* grasses (Figure 3-12) were distributed in small patches (Appendix Q) along banks and sandbars throughout the Warrior River basin between the dam and Tuscaloosa.

In general, the aquatic macrophytes of the Middle Black Warrior and Tombigbee River basin were observed to be distributed throughout the study area. Most of the submerged and floating "water weeds" (e.g. alligator weed) were confined to banks, littoral zones, sloughs, embayments and creek mouths. Thus, no hazard to main river channel is posed by present plant growth. However, fishermen and sport boaters will often encounter floating mats and dense stands of alligator weed and water willow in the shallower portions of the rivers. This will be particularly true in such areas as creeks, sloughs and around or between islands (see Appendix Q).

#### DISCUSSION

# 4.1 Overview of Water Quality Characteristics of the Middle Black Warrior-Tombigbee River System

The Middle Black Warrior and Tombigbee Rivers display unique patterns of basline water quality. The sources of distinction between the two river basins would appear to be caused by three (3) major controlling factors (in presumed order of importance):

- geochemical characteristics of the individual watersheds
- O patterns of cultural water resource exploitation
- o amount and extent of impoundment

These factors combine in such a way that a single description of the water quality of the Middle Black Warrior and Tombigbee Rivers is not possible.

To provide some insight into the specific differences in water quality, Table 4-1, which displays the grand average for various constituents in each basin, was prepared. Included in this table is the grand average for the water quality parameters monitored in Demopolis Lake.

Cursory review of this tabulation reveals several major trends in the different basins. The Tombigbee River has a lower clarity than did the Black Warrior River, as indicated by the depth 1% light remains (euphotic zone), turbidity, transparency and color. Alkalinity, hardness, calcium chlorides, non-filterable residue, dissolved and total iron were consistently higher in the Tombigbee River while dissolved minerals (magnesium, sodium, potassium), ammonia, nitratenitrite sulfates, manganese and zinc were lower in the Tombigbee River. pH levels were circumneutral, dissolved oxygen was well above the aquatic life criterion of 5.0 mg/l and temperatures averaged 24.00 + 0.20C in all basins. These average values indicate that various processes are at work creating different physical-chemical water quality characteristics in the two main rivers. It should be noted that for all but two parameters (temperature and potassium), the parameter values for Demopolis Lake are between or equal to, the values in the main rivers.

In contrast to the distinct differences in physical-chemical constituents, the aquatic biota in the rivers were essentially similar. The major differences arose in the total numbers of organisms in the plankton or the benthos. As can be seen on Figures 3-1 through 3-4, the total numbers (or biomass in the case of benthos) are the lowest in the "free flowing" sections such as the Upper Warrior Lake and the Tombigbee River at R-17 and R-18. It would appear that the water quality differences between the two rivers are not great enough to alter the biota significantly.

Summary of Average Water Quality Conditions, Middle Black Warrior and Tombigbee Rivers, July 1978 thru November 1979 TABLE 4-1.

These trends indicate that the major influences producing the baseline water quality differences between the two rivers are the geochemical makeup of the river basin and the amount and nature of cultural input received. The geochemical aspect is especially important on the Black Warrior River, where drainage and run-off from the surface mining activity and the specific area geology is responsible for increased levels of such constituents as sulfates, iron, manganese, zinc and total dissolved solids. The Tombigbee River, which shows higher levels of suspended solids, phosphates, organic nitrogens and organic carbons, is assumed to be receiving greater amounts of agricultural run-offs. These two major influences, each dominant in a separate river basin, appear to be the primary sources of water quality variation between the two basins.

The effects of impoundment were less quantifiable than the other two causes of water quality variation. Neither the Tombigbee River nor the Black Warrior River, with its more extensive impoundment, showed any severe effects such as complete deoxygenation of deep waters which are often associated with impoundment. Biological productivity, especially as measured by numbers of phyto- and zooplankton, was somewhat affected by the impoundments. The slowing and widening of the river, with a concomitant increase in the volume of the euphotic zone, produced an obvious increase in plankton numbers in both Warrior Lake and Demopolis Lake (see Figures 3-1 and 3-2). Benthos differences were primarily noted as increased biomass in the lacustrine sections (Figure 3-3). Interestingly, Shannon-Weaver diversity values did not vary much in the lake sections, although examination of the species composition (e.g. Appendix N-3) will show some degree of change between the riverine and lacustrine secitons. Impoundment apparently had more effect as a "ponding" situation (as regards the biota) than it did in producing physical-chemical stratification. The Middle Black Warrior and Tombighee Rivers have distinctly differing water quality characteristics. These characteristics are produced by differing geological features in the river basins as well as the extent and nature of water resource exploitation. The impoundment of the Black Warrior River at Warrior Lake and Demopolis Lake appears to have no effect on overall water quality, but does increase biological productivity. The average water quality in each basin in unique, but the seasonal variations produce wide ranges of concentrations in most of the studied parameters.

# 4.2 <u>Variation of Water Quality in the Middle Black Warrior and Tombigbee Rivers</u>

The major trend observed for the Middle Black Warrior and Tombigbee Rivers system was the extreme seasonal variation in levels of most monitored parameters. For the majority of the physical-chemical parameters experiencing these seasonal fluctuations, the general pattern was summer minima with late winter or early spring maxima. Additionally, when certain parameters are evaluated on a "concentration versus downstream distance" plot across several seasons, variations in the relative concentrations between stations are revealed. These water quality characteristics appear to be most affected by seasonal patterns of rainfall and subsequent patterns of flow and flooding. The second maxima and minima of various indicator water quality constiuents and biological communities follow the patterns of rainfall increase and decrease.

Figure 4-1 illustrates the total daily precipitation at four stations within the study area. As can be seen, precipitation was more prevalent during the late winter (December 1978 thru February 1979) and on into the spring (thru late April 1979). The heaviest rains occurred in mid-April 1979 with a one day maximum of 10.2 inches (a study area ide average for that same period was 6.8 inches, with the lowest rainfall being recorded at the most downstream station). This rainfall coincided with several floodings throughout the Middle Black Warrior-Tombigbee River basins. This pattern of precipitation closely coincides with variations of several major parameters.

Because of the magnitude of the present study, not all investigated parameters will be considered in relation to seasonal patterns. However, several parameters have been condisered in this manner, and these parameters generally represent several related parameters. In the same way, four stations, one in each river section, have been chosen to represent typical concentrations of these parameters during each sampling. In the downstream analyses, three dates have been chosen to represent 'critical' periods during the study, i.e. summer 1978, spring 1979 (after the heaviest rainfalls) and late summer 1979 (low flow). These combinations will allow for explication of the seasonal patterns of physical chemical parameter increase and decrease.

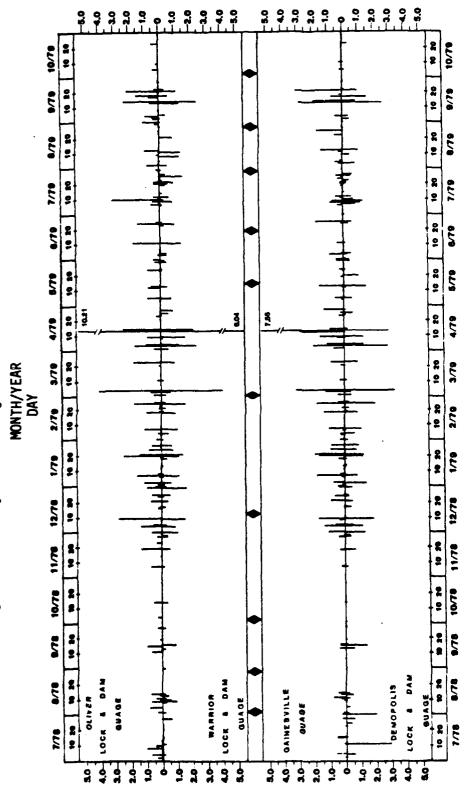

The direct effects of precipitation on water quality come from drainage basir run-off. A principal effect of this run-off is an increase in the suspended sediments loading to the main river. Figure 4-2 illustrates the response of non-filterable residue (total suspended solids) to increased levels of precipitation. Warrior Lake, represented by station R-2, showed little variation in suspended solids loading at any time during the study. All other representative stations exhibited drastically increased suspended solids loadings during sampling trips 5 and 6, which coincides with the increased mid-to-late winter increases in precipitation. The depth of the euphotic zone (Figure 4-3) shows this same general pattern, displaying marked decrease of light penetration during these same samplings. These two parameters are representative of all measures of clarity (see Section 3.1.1). Of note, specific conductance, (Figure 4-4) which is a measure of total ionized substances, was lower during the periods of rainfall (and the colder months in general), perhaps indicating direct dilution by the purer rainwaters with less geological contact time in which to dissolve mineral constituents.

Other parameters which play a significant role in overall water quality are nutrients and metals. Nutrient additions affect the biological communities by stimulation of algal growth. Algal metabolites can produce taste, coloration and even health problems which might limit water use. Orthophosphates and inorganic nitrogen (TIN) are the major nutrients needed for plant growth (U.S.E.P.A. 1978). These two parameters show less direct influence by total rainfall than other parameters. However, orthophosphates (Figure 4-5) do show a general trend of increase throughout the spring and summer. The high orthophosphate concentration recorded in August 1979 may have been related to agricultural applications of fertilizer being contributed by run-off during this period. TIN (Figure 4-6), while it did increase at two stations after the intense rainfall, reached its highest levels in June 1979, possibly indicating fertilization practices. The two heavy metals most intensly studied, iron and manganese (Figures 4-7

and 4-8, respectively), both reached their maximum concentrations during the flood season.

While these metals became more prevalent during the flood season, it should be noted that, because both of these elements are common in sediments (see Appendix J), extremely elevated values may represent a direct correlation with increased suspended sediments and not actual high ionic concentrations of all heavy metals. These example parameters indicate that seasonal patterns of constituent concentrations in the Middle Black Warrior-Tombigbee Rivers are controlled by climatological factors such as rainfall and perhaps cultural practices such as the application of fertilizers in the spring.

An analysis of concentration versus distance reveals more distinct downstream trends and relationships between the river basins during several seasons. Figure 4-9 illustrates the concentrations of dissolved cxygen (DO) at the five foot depth in the entire study area during three samplings. This figure clearly demonstrates the overall high DO for all river sections and indicates a good assimilative capacity (e.g. the low DO levels at T-4 during all months, are quickly mitigated by the time the water passes R-6). Specific conductance (Figure 4-10) also displayed a relatively constant level and good assimilative capacity (see D-3, October 1979).

Other parameters appear to be more influenced by drainage basin characteristics or impoundment. Two examples of this pattern are nonfilterable residue (suspended solids) and inorganic nitrogen (TIN). Suspended solids (Figure 4-11) were quite high during the flood period (see above). Another interesting feature, however, is the marked decrease in suspended solids loadings downstream of Warrior Lock and Dam (below R-9). The decreased water velocity within the impoundment is apparently allowing for sufficient settling to decrease suspended solids downstream. TIN (Figure 4-12) displays very constant downstream concentrations in the Black Warrior River with distinctly lower values in the Tombigbee River.

Orthophosphates, the other essential plant nutrient, has a more distinct seasonal pattern of increase (Figure 4-13). The May 1979 sampling proved to have much higher levels of this nutrient. The Tombigbee River had elevated values during all 1979 samplings (Appendix A) with May 1979, shown here, being the greatest. The metal parameters routinely analyzed, total iron (Figure 4-14) and total manganese (Figure 4-15) display very different trends. Total iron is constantly higher in the Tombigbee River after the intense rainfalls, while the Black Warrior River maintained relatively stable levels at each station. Total manganese showed a one time increase in the spring 1979 and returned to its 1978 levels. Like iron however, manganese was much higher in the Tombigbee River than in the Black Warrior River.

The analysis of selected water quality parameters reveals patterns of seasonal and river basin associated variation. The occurrence of severe flooding during the middle of this study produced conditons of elevated loadings of many parameters. Other inputs, such as agricultural run-off appear to influence water quality as well. This combination of natural and cultural influences produced distinct and unique water quality characteristics in the Middle Black Warrior and Tombigbee Rivers.

#### SECTION 5

### RECOMMENDATIONS

- 1. Continuation of Study. Due to the apparent extreme effects the May 1978 flooding produced, it is recommended that monitoring continue to assess the degree of impact produced by fluctuating flow conditions.
- 2. <u>Decrease Sampling Points.</u> The homogeniety of the Black Warrior River indicates that fewer stations are needed.
- 3. Tributary Stations. It is recommended that in future studies, the investigation of tributaries be discontinued and at those suspected of impacting the river proper be investigated as "above-below" situations to assess the in-stream quality in the immediate area.
- 4. <u>Stratification.</u> This study revealed no major points of stratification in the Middle Black Warrior and Tombigbee Rivers, thus stratification studies could be ceased during future investigations.
- 5. <u>Sediments</u>. Sediments in and around Tuscaloosa should be studied further (e.g. toxicity evaluations) if dredging is needed below Oliver Lock and Dam.
- 6. <u>Macroinvertebrates</u>. The scale and usage of multiple plate samplers dictate for this study was not effective and it is recommended this non-comparative device be eliminated from further use in future studies.

## TABLE Q-3. continued

The second secon

"Association A" is given for many localities in Table 4. Thi association consists of the following plants:

Barnyard Grass
Eragrostis glomerata
Eragrostis hyproides
Ammonnia coccinea
Finbristylis vahlii
Ludwigia decurrens
Lindermia anagallidia
Panicum agrostoides
Panicum dishotomiflorum
Marsh Fleabane
Cyperus erythrorhizos
Cyprus strigasus
Cutgrass (Leersia)

Although these plants are listed in estimated order of abundance, the estimation is pure guesswork as all these plants are close to being equal in abundance. There is no most abundant species in Association A, though Alligator Weed and especially Giant Cutgrass are often present as most abundant species.

The second of th

Associations listed in Table 12.

#### Association V:

No "most abundant" species
Cockelbur
Willow
Cutgrass
Erogrostis glomerata
Fimbristylis vahlii
Lippia nodiflora
Paricum dichotomiflorum
Lindermia anagallidia
Halberd-Leaved Marsh Mellow
Eclipta alba

### Association VI:

No "most abundant" species
Marsh Fleabane
Alligator Weed
Erogrostis Hup noides
Erogrostis glome rata
Lindernia anagallidia
Gamma Grass
Cyperus erythrorhiaos
Cyperus articulatus
Panicum dichotomiflorum
Panicum agrostoides
Lippia nodiflora
False Nettle
